Weekend Margin

Clearinghouse

An on-chain clearinghouse for Bitcoin perpetual swaps that takes tokenized T-bills as margin and still pays winners on a Saturday

FRE-GY 6931 Blockchain & Cryptocurrency · Fall 2026 · **Team 9**

Sai Kishore	(sp8744)	contracts, deployment, front end
Swastik Mishra	(sgm9198)	financial analysis, product, going to market

Prof. Richard Radnay · TA Hina Tomar · November 4, 2026

Topic	2 — Hedging with perpetual swaps
Network	Ethereum Sepolia
Our token	**sBILL** — Tokenized T-Bill Share (ERC-20), 0x2aff94631070707436ef712c4a6e77ecaf4c6720
Contracts	16 deployed, **16 verified on Etherscan**
Repository	https://github.com/Psaikishore/WeekendMarginDemo tag final
Evidence	submission.json in the repository root

Every token in this project is a test token with no value. Nothing here is investment advice.

Where to find everything

The brief lists six deliverables. The table below says where each one is.

#	Deliverable	Where it is
1	Contracts on Sepolia, including our token, verified on Etherscan	All 16 addresses in **Section 3.5**; verification and metadata in §3.6; Etherscan screenshots in §3.7; every function tabulated in §3
2	GitHub repository, tagged `final`, with a README	`https://github.com/Psaikishore/WeekendMarginDemo`; the README explains what the project does and how to run the tests
3	`submission.json`	Repository root; its structure is in **Appendix C**; the eight key transactions are in **Appendix A**
4	Report (PDF) under the eight required headings	This document, `docs/report.pdf`
5	Financial analysis in `docs/`	`docs/analysis.ipynb`, summarised with its charts in **Section 4**; the business case is **Section 6**
6	Video: narrated, every member speaks, at least one live Sepolia transaction	Linked in `submission.json`; the running application is described in §3.9

The one-sentence version. A fund can keep its money in Treasury bills, earning interest, and still pay what it owes on a Sunday — because when the T-bill market is shut, a permissionless vault of investors' cash buys the fund's T-bill tokens at a small discount, pays the winner immediately, and redeems the tokens on Monday for the difference.

1 Objective

1.1 The problem, in one picture

Bitcoin trades every hour of every day. Banks and the Treasury bill market do not. They shut on Friday afternoon and open again on Monday morning — a gap of **65 hours** in which the world's safest asset cannot be turned into cash.

Now put a hedger in that gap. A fund owns Bitcoin and does not want the price risk, so it shorts a perpetual swap. That is a good trade and a standard one. But a perp settles continuously: if Bitcoin rises on a Saturday, the short owes cash on Saturday. Its safest asset, a Treasury bill paying about 4% a year, cannot be sold until Monday.

So the fund does the only thing it can. It keeps a pile of cash sitting idle, all year, for the handful of weekend hours it might be needed. That cash earns nothing.

> **The problem is current.** About $19bn of open crypto positions were liquidated within roughly 36 hours on 10–11 October 2025 [17]. CME Group has traded crypto futures and options around the clock since May 2026, but weekend trades still carry the next business day's trade date and are cleared and settled on that day [18, 19]. The timing mismatch exists today, and it is large.

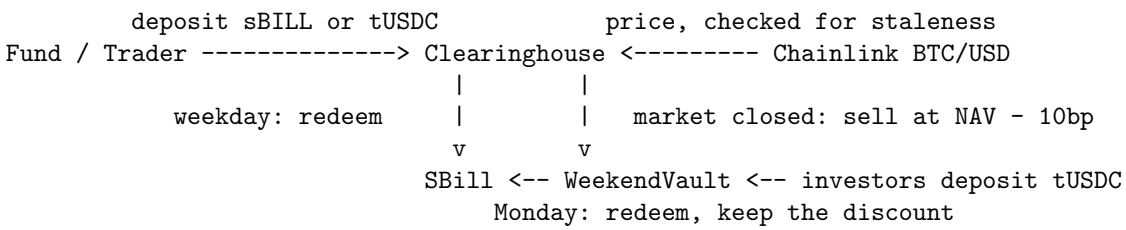

1.2 What we built

A buyer of T-bill tokens that is open all weekend.

If a fund needs cash on Saturday, our vault buys its tokenized T-bills for $0.999 on the dollar. On Monday the vault redeems them for $1.0000 and keeps the difference. Three things happen that cannot happen today:

- **The fund** pays a few basis points, only when it actually needs cash, and earns T-bill interest for the rest of the year instead of holding idle cash.
- **The winner** is paid on Saturday, not Monday. No IOU, no counterparty exposure overnight.
- **The vault's investors** earn the discount.

No bank has to be open. No person has to approve anything. No custodian sits in the middle. The clearinghouse reads its collateral's redemption calendar directly and routes settlement accordingly, which is what makes an automatic payment on a Sunday possible.

1.3 Why we chose this

We chose Topic 2, hedging with perpetual swaps, for three reasons.

1. **It is a real financial problem with a real number attached.** A hedge that cannot be funded is not a hedge. We could measure exactly what the gap costs and exactly what closing it is worth, which meant the analysis would have an answer rather than an opinion.
2. **The course requires every project to mint and use its own token.** That requirement pushed us somewhere interesting. A perp alone does not need a token. A perp *margined with a tokenized Treasury bill* needs one — and the moment the collateral has its own redemption

calendar, the weekend problem appears and the whole design follows from it. The token is central to the design rather than an addition made to satisfy a rule.

3. **The market was moving in this direction while we built.** Circle shipped a 24/7 BUIDL-to-USDC contract in April 2024 [1]. Binance accepted Circle's USYC as off-exchange collateral in July 2025 and BlackRock's BUIDL that November [2, 4]. Deribit and Crypto.com followed [3]. Every one of those validated our premise: institutions want to post interest-bearing collateral, and the settlement calendar is what stands in the way.

1.4 What we expected, and what actually happened

We wrote our expectations down at the proposal stage. Three of them turned out to be wrong, and those three taught us the most.

What we expected	What we found	Why it matters
A 10bp weekend discount would be about right.	10bp covers the risk of *each use* (6.6bp needed) but the vault still earns only 1.2–1.7% a year against 4.01% on T-bills. A real vault needs 28–44bp.	The cost is not the weekend. It is the three quarters of the vault's cash that sits idle waiting for one. We report this rather than redeploying with a different number (§4.6).
Weekends are more dangerous than weekdays.	Per hour, weekends are *calmer*: hourly volatility 0.52% inside closures against 0.68% outside.	The weekend problem is that the T-bill market is shut, not that Bitcoin misbehaves. That reframed the whole design (§4.5).
The main risk to a hedger is price.	The main risk is *liquidation*. With no top-ups the demo's short is liquidated in 14% of 30-day windows, and about half at maximum leverage.	A liquidated hedge leaves the fund naked at the worst possible moment (§4.4).
Gas would be a detail.	At 100 open trades, hourly settlement on Ethereum mainnet costs $1.90m a year against roughly $30k of revenue.	The product cannot exist on mainnet. This single measurement decides where it can ship (§6.7).

1.5 What we promised and what we delivered

The professor's feedback on our proposal	Where it is answered
Financial analysis: hedged vs unhedged P&L, funding, liquidation price, vault economics including the discount needed given the T-bill yield and weekend price risk	§4, all of it, plus `docs/analysis.ipynb` sections A–E
A going-to-market plan	§6, with a break-even number and a costed P&L
Build the end-to-end path first	Done in that order: contracts, then tests, then Sepolia, then front end, then analysis
How does "weekend" work on Sepolia, and who can change the calendar?	Two calendars, §3.4. The production one has no owner. The demo one's switch is held by the deployer, and we say so everywhere
Staleness limit above 1 hour	2 hours, against the feed's roughly 1-hour heartbeat (§3.8)
Risks: BUIDL and BENJI holder restrictions	§6.8, risk 2

2 Design decisions

Most of the choices below were made twice: once at the start, and again after a measurement showed that the first choice was wrong. Those are marked **changed**.

2.1 The core architecture

Decision	What we considered instead	Why we chose as we did
Bilateral trades — each trade has exactly one long and one short	A shared pool, as most perp DEXs use	Losses are never spread onto uninvolved users, and the accounting is simple enough to reconcile to the wei. The cost is real and we state it: when one side is liquidated, the other side's hedge ends too.
Our own token is the collateral, not a reward coin	A governance or points token, which is the usual Web3 answer	The entire pitch is that a fund knows what its collateral will realise. A token that subsidises deposits makes the vault's advertised return a function of that token's price, which re-introduces exactly the volatility the customer came to remove (§6.5).
ERC-4626 for the vault	A bespoke share accounting scheme	Standard, audited, and every wallet and aggregator already understands it.
One market, one position per account	A general portfolio margin engine	A two-person team with four weeks. We chose depth on the weekend mechanism over breadth.

2.2 Five things we changed because measurement told us to

2.2.1 Packed storage — changed after measuring gas

Our first version cost **244,696 gas** to open a trade, by far the most expensive thing a user does. Almost all of it was storage: a new slot costs about 22,100 gas, and the `Trade` struct used six of them. A `bool` took a whole 32-byte slot. A timestamp took 32 bytes when 5 will do.

Before — six slots	After — three slots
`address long; address short; uint256 size; uint256 lastPrice; uint256 lastSettledAt; bool open;`	`address long; uint40 lastSettledAt; bool open;` (slot 1) `address short; uint96 size;` (slot 2) `uint128 lastPrice; int128 lastFunding;` (slot 3)

Three fewer new slots at 22,100 gas each predicts a saving of 66,300. We measured **65,337**. On Sepolia, where storage is dearer still, `acceptOffer` fell **33.6%** and `postOffer` **27.3%**. `SafeCast` reverts if a value ever would not fit, and the ranges are far larger than needed: `size` as `uint96` holds billions of BTC, and `lastSettledAt` as `uint40` lasts for about 35,000 years. Full numbers in §5.3.

2.2.2 Funding as a running total — changed after reading our own code

Our first version multiplied the *current* funding rate by all the time since the last settlement. On a trade left unsettled for 30 days, the owner could post the maximum rate and charge it backwards: $0.1\% \times 720$ hours $= 72\%$ of the position, instantly. On an \$80,000 position that is \$57,600 taken from a user by an admin action.

The contract now keeps one running total, `cumulativeFunding()`, and **a new rate applies only from the moment it is posted**. Each trade remembers the total at its last settlement and owes the difference. There is a test for it.

> **No scanner found this.** Slither did not flag it, because it is a finance error rather than a code pattern. We found it by reading the code and asking what the worst thing an owner could do was. We would ask that question first next time.

2.2.3 A 65-hour calendar — changed so the contract matches the analysis

The first `MarketCalendar` closed for 48 hours: Saturday and Sunday, UTC. The analysis used the real market closure, Friday 4pm to Monday 9am ET, which is 65 hours. Two numbers that should have been one. The contract now closes Friday 21:00 to Monday 14:00 UTC — the same 65 hours — and the notebook reads the contract's own value back to prove it (§4.9).

2.2.4 An adjustable discount inside a hard limit — changed after the analysis

We deployed with 10bp. The analysis then showed 10bp is too low for a vault to be a business. We could have re-deployed; instead we made the discount owner-adjustable **up to a hard cap of 1%, and only while the market is open**, and the cap itself cannot exceed the weekend haircut — the clearinghouse refuses to deploy otherwise. So a forced weekend sale can never surprise the margin engine, and the price can still respond to rates without touching the code.

2.2.5 A third, clearly-labelled set of contracts with a mock price

A real liquidation at the demo's size needs Bitcoin to move about 25%. Waiting for that move is not practical, and unit tests alone are weaker evidence than a live transaction. So we deployed a third set whose price feed is a mock anyone can move, labelled `Stress` in every address, document and page.

The script does something better than simply forcing a liquidation: it computes the liquidation price from the formula in §4.4, shows the contract *refusing* at 0.1% below it, and then liquidating at 0.1% above it. That checks our formula against the deployed code, rather than only showing that a liquidation can happen.

> **The report must say this, so we say it here and again in §3: the stress set's Bitcoin price is a mock, and the demo set's weekend is a switch held by the deployer.** The production design is the Main set, which uses the real Chainlink feed and a calendar nobody can change.

2.3 Nine smaller choices, with the reason

Choice	Reasoning
Two calendars, not one with an offset *(changed)*	We first gave the real calendar a fixed time offset for demos. But that only shifts *which* real days count as the weekend, so the demo still depended on the recording day. Now the real calendar has no admin at all, and a separately named copy carries the switch.
Fixed 4% NAV, not a posted NAV *(changed from the proposal)*	A keeper posting NAV is another trusted role and another thing to attack. A fixed rate has none. The cost: our token cannot show T-bill *price* risk, which is 72% of the fee we charge for it (§4.11).
2-hour staleness limit	Sits above the feed's roughly 1-hour heartbeat, so a normal gap does not stop settlement, while a genuinely dead feed does.
Vault inventory held at cost, withdrawals capped at cash	The share price never shows a gain the vault has not actually collected, and a depositor cannot drain cash that is owed to a settlement.
Two mirrored demo trades	With one trade, a price move in the wrong direction would never touch the vault and the demo would show nothing. With a long pair and a short pair, one sBILL-backed fund has to pay whichever way Bitcoin moves.
Deribit for funding data	The brief names BitMEX; its API returns 403 from our US network. We checked Deribit's hourly `interest_1h` against its own 8-hour series: correlation 0.9997.
Sepolia gas price of 0.05 gwei	The default tip was draining a small test wallet for no benefit on a quiet testnet.
Rounding always against the party being paid	Contract division rounds. We round so the system can never pay out more than it holds. The notebook copies the same rules, which is how it matches to the last of 18 decimals.
Anyone can call `settle` and `liquidate`	No privileged keeper. Our keeper script is a convenience, not a dependency, and the 0.5% liquidation reward means a stranger is always motivated to clean up a bad position.

2.4 The user's side: what the interface does to stop costly mistakes

A clearinghouse that is correct on-chain and opaque in the browser is not trustworthy. Four protections are built into the front end, and every one can be inspected in the repository.

- **Plain-English errors, everywhere.** `utils/weekend/errors.ts` maps **27 custom errors** — ours and OpenZeppelin's — to sentences that say what happened and what to do, with fallbacks for a rejected signature and for running out of gas. It is wired into the *shared* transaction path, so it covers every call the app can make rather than a hand-picked few. A user who posts too large a trade reads "Your margin is too low for this. Deposit more, or use a smaller size" — not `InsufficientMargin(1, 2)`.
- **Two clicks for anything irreversible.** The shared button takes a `confirmText`; the first click only asks. It guards the four actions that cannot be undone: opening a trade, closing one, liquidating a counterparty, and pausing the system. Closing reads "This settles at the current price and ends the trade for both sides."
- **Impossible actions are disabled with a stated reason.** There are **24 `blockedBecause` guards** across the five application pages and the shared components. A button that cannot work is greyed out and says why — no wallet, stale price, empty amount, owner-only — so nobody pays gas to discover a revert.
- **The liquidation price is shown *before* the trade opens**, for both sides, recomputed from the same formula the contract uses as you type the size and margin. When the Chainlink price is stale or unset, a banner says that new trades and settlement are waiting.

Why there are no slippage limits. There is no pool and no order book to walk, so there is no price impact to bound. A trade opens at the Chainlink price both sides can read before committing, and a weekend sale to the vault executes at NAV minus a discount fixed in contract storage. The fill is deterministic and known in advance, which is a stronger guarantee than a tolerance band. The limit of this is that the price is only as good as the oracle, which is why the two-hour staleness check and the banner exist.

3 Architecture

3.1 Six contracts, and what each one is for

Contract	Base	What it does
`SBill`	`ERC20`	**Our minted token.** A mock tokenized T-bill fund share. Its NAV grows at a fixed 4% a year on the clock, weekends included. `subscribe()` and `redeem()` only work while the market is open — this one restriction is the entire reason the rest of the system exists.
`TestUSDC`	`ERC20`, `AccessControl`	Test dollars, 18 decimals, with a public faucet of 100,000 per address per hour so anyone can try the app without asking us for anything.
`MarketCalendar`	—	Answers one question: is the T-bill market open? Closed Friday 21:00 to Monday 14:00 UTC, 65 hours. **No owner, no settings, no admin.** Nobody, including us, can change when the weekend is.
`DemoCalendar`	`Ownable`	A separately named copy with an owner's switch, so the weekend path can be shown on any day. Used *only* by the Demo and Stress sets.
`WeekendVault`	`ERC4626`, `Ownable`	The weekend buyer. A pool of investors' tUSDC that buys sBILL at NAV minus a discount — only from the clearinghouse, and only while the market is closed. Anyone can trigger redemption on a business day. Inventory is held at cost and withdrawals are capped at cash.
`Clearinghouse`	`Ownable`, `Pausable`, `ReentrancyGuard`	The central contract. Holds margin, matches offers into bilateral trades, settles price moves and funding, converts collateral when the loser has no cash, and liquidates.

3.2 Every public function

`Clearinghouse` — **the central contract**

Function	Who	What it does
`depositUsdc(amount)`	anyone	Adds tUSDC margin. Blocked while paused.
`depositSBill(amount)`	anyone	Adds sBILL margin, valued at NAV minus the haircut.
`withdrawUsdc(amount)`	anyone	Settles first, then refuses if it would break initial margin. **Works even while paused.**
`withdrawSBill(amount)`	anyone	As above, for sBILL.
`postOffer(isLong, size)`	anyone	Advertises one side of a trade. One offer per account.
`cancelOffer()`	maker	Withdraws it.
`acceptOffer(offerId)`	anyone	Opens the trade at the live Chainlink price. Checks initial margin for both sides.
`settle(tradeId)`	**anyone**	Pays the price change plus funding from loser to winner. The heart of the system.
`closeTrade(tradeId)`	either side	Settles and ends the trade. Works while paused.
`liquidate(tradeId)`	**anyone**	Settles, then closes the whole trade if either side is below maintenance. Pays the caller 0.5% of notional.
`setFundingRate(rate)`	owner	Capped at 0.1%/hour, and applies only from this moment onward.
`pause() / unpause()`	owner	Stops *new* deposits, offers and trades. Never stops settlement, closing, liquidation or withdrawal.
`latestPrice()`	view	Chainlink BTC/USD, rejected if older than 2 hours or non-positive.
`cumulativeFunding()`	view	The running funding total per dollar of position.
`haircutBps()`	view	100 while open, 300 while closed.
`collateralValue(who)`	view	tUSDC + sBILL×NAV×(1 − haircut).
`unsettledPnl(who, price)`	view	**Unrealized profit and loss** on the open position.
`accountHealth(who)`	view	Returns equity, maintenance margin and initial margin together.
`requiredMargin(size, price, bps)`	pure	The margin arithmetic, exposed so the front end and the notebook use the contract's own formula.

`WeekendVault` — **the weekend buyer**

Function	Who	What it does
`deposit / withdraw / mint / redeem`	anyone	Standard ERC-4626. `maxWithdraw` and `maxRedeem` are overridden to cap at `cash()`, so sBILL waiting for Monday cannot be withdrawn.
`buySBill(usdcOut)`	**clearinghouse only**	Pays cash, takes sBILL at `purchasePrice()`. Reverts with `MarketOpen` on a business day and `InsufficientLiquidity` if the cash is not there.
`redeemInventory()`	**anyone**	Redeems the vault's sBILL with the fund at full NAV and books the profit. Business days only.
`setDiscount(bps)`	owner	Up to the immutable `maxDiscountBps`, and only while the market is open.
`setClearinghouse(addr)`	owner	**Can only be called once**, ever.
`cash() / totalAssets() / purchasePrice() / quoteSBillIn() / quoteUsdcOut()`	view	Pricing and accounting, all public so anyone can check the vault's books.

`SBill` — our token, and the two calendars

Function	Who	What it does
`SBill.nav()`	view	$10^{18} + 10^{18} \times \text{apyBps} \times (\text{now} - \text{start})/(10{,}000 \times 365 \text{ days})$
`SBill.valueOf(shares)`	view	shares × NAV, rounded down.
`SBill.subscribe(usdc)`	anyone	Mints shares at NAV. **Reverts `MarketClosed` at weekends.**
`SBill.redeem(shares)`	anyone	Burns shares, pays NAV. **Reverts `MarketClosed` at weekends.**
`MarketCalendar.isOpen()`	view	Pure arithmetic on `block.timestamp`. No state, no owner.
`DemoCalendar.setWeekend(bool)`	**owner**	The labelled demo switch. Emits `DemoWeekendSet`.
`*.isDemo()`	view	Returns `true` on the demo calendar, `false` on the real one, so the front end can label the deployment it is reading.

3.3 How the money actually moves

One settlement, written as the contract decides it:

```
Does the loser have enough tUSDC?
 |-- Yes -> take it. Done.
 `-- No  -> take all its tUSDC, then raise the rest by selling sBILL:
             Is the T-bill market open?
              |-- Yes -> redeem with the fund, at full NAV.
              `-- No  -> sell to the WeekendVault, at NAV minus the discount.
                         Does the vault have enough cash?
                          |-- Yes -> the winner is paid, on a Saturday.
                          `-- No  -> the whole transaction reverts.
                                     Nothing happens at all.
```

```
If the loser's sBILL runs out too, the winner receives what was collected and
the shortfall is recorded. The Settled event carries both amountDue and
amountPaid, so any underpayment is visible on-chain forever.
```

That last branch is the main weakness of the design, and we state it clearly: **there is no insurance fund**, so a large enough gap move can leave a winner underpaid. The shortfall is visible on-chain rather than hidden, and §6.8 says what a production version would do about it.

3.4 Three deployments, and why

Set	Calendar	BTC price	What it is for
Main	Real, *nobody* can change it	Chainlink	**The production design.** No trades, empty vault. This is the one a real product would use.
Demo	Owner's switch	Chainlink	The demo, the video and the reconciliation. 50,000 tUSDC in the vault; Fund A short vs Trader B long, and Fund C long vs Trader D short, each 1 BTC on 30,000 of margin. The funds post sBILL and the traders post tUSDC, so whichever way Bitcoin moves one sBILL-backed fund has to pay.
Stress	Owner's switch	**Mock, anyone can move it**	Showing a liquidation, which would otherwise need a 25% Bitcoin move. **Clearly labelled as a mock price everywhere.**

3.5 Contract addresses

All sixteen contracts are deployed on Sepolia and **all sixteen are verified on Etherscan**. Every address below is a live link. The Chainlink BTC/USD feed we read is

0x1b44F3514812d835EB1BDB0acB33d3fA3351Ee43.

3.6 Verification, compiler and metadata

Verification was confirmed through the Etherscan API rather than by eye, and we then compared the verified source Etherscan serves back against the files in this repository. **For the fifteen contracts we checked, the verified source is byte-identical to the repository.**

Setting	Value
Compiler	`solc 0.8.30+commit.73712a01` (pinned exactly in `hardhat.config.ts`)
Optimizer	enabled, `runs = 200`
EVM version	`prague`
Licence	MIT, declared with SPDX in every file
Libraries	OpenZeppelin Contracts — `ERC20`, `ERC4626`, `Ownable`, `Pausable`, `ReentrancyGuard`, `AccessControl`, `SafeERC20`, `SafeCast`, `Math`, `SignedMath`; Chainlink `AggregatorV3Interface`
Per-contract metadata	`packages/hardhat/deployments/sepolia/*.json` — ABI, bytecode, deployed bytecode, immutable references, storage layout, devdoc, userdoc, constructor arguments and the full deployment receipt, for all 16

Machine-readable artefacts in the repository (also listed in Appendix C):

File	What it holds
`submission.json`	Team, members and NetIDs, topic, repository, tag, network, the token, all 16 contracts with their role, 8 key transactions, 9 features with evidence, video link
`packages/hardhat/deployments/sepolia/`	16 JSON artefacts: ABI, metadata, storage layout, receipts
`packages/nextjs/contracts/deployedContracts.ts`	Generated typed ABIs the front end reads
`packages/hardhat/demo-log.sepolia-demo.json`	Every transaction hash from the demo run, step by step
`packages/hardhat/demo-log.sepolia-stress.json`	The same for the liquidation run
`config/protocol.json`	The eight settings the contracts are deployed with
`config/assumptions.json`	Every judgement call in the analysis, in one place
`config/analysis_results.json`	The notebook's own output, consumed by the app's Economics page
`docs/data/sepolia_reconciliation.csv`	The model-vs-chain comparisons of §4.9

3.7 On-chain evidence

Four pages from Etherscan. Each one can be opened from the links in §3.5 and Appendix A, and the numbers in them are the same numbers the model reconciles against in §4.9.

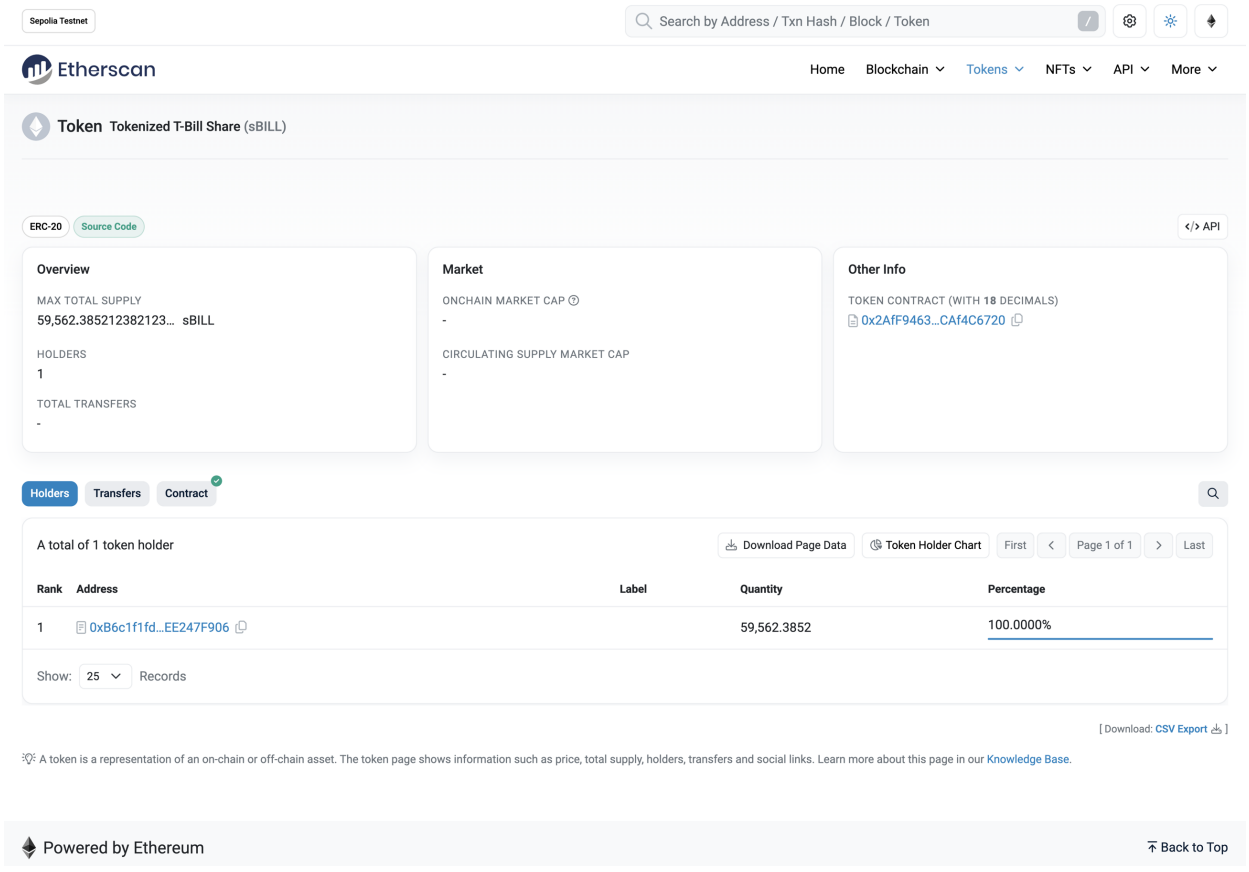

Figure 1: Our minted token on Sepolia. `Tokenized T-Bill Share (sBILL)`, ERC-20, 18 decimals, with the green *Source Code* badge. The supply shown is the sBILL the demo funds subscribed for.

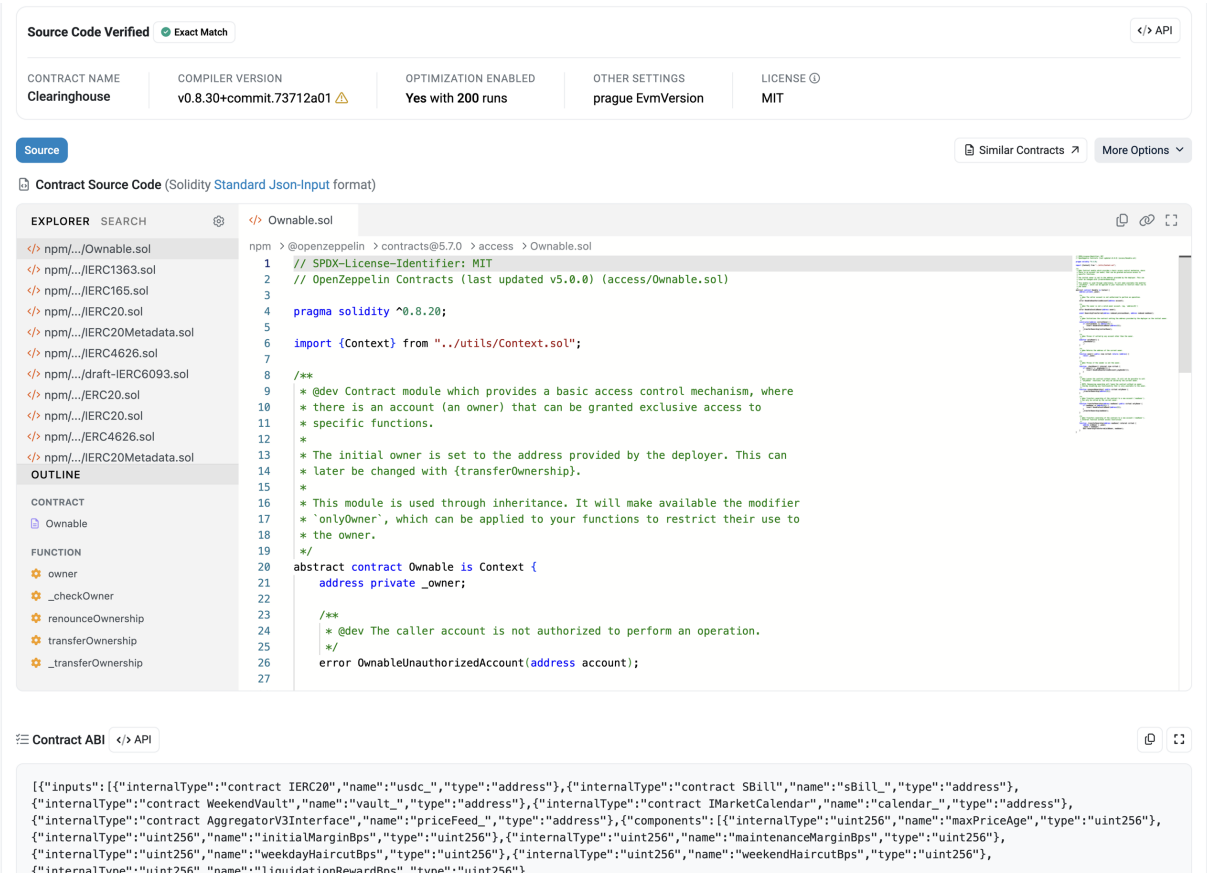

Figure 2: Verified source, and the compiler settings behind it. `Clearinghouse` on Etherscan: *Source Code Verified* — *Exact Match*, `v0.8.30+commit.73712a01`, optimizer on at 200 runs, `prague` EVM version, MIT. These are exactly the settings tabulated in §3.6, read off the chain rather than off our own build. All sixteen contracts show this badge.

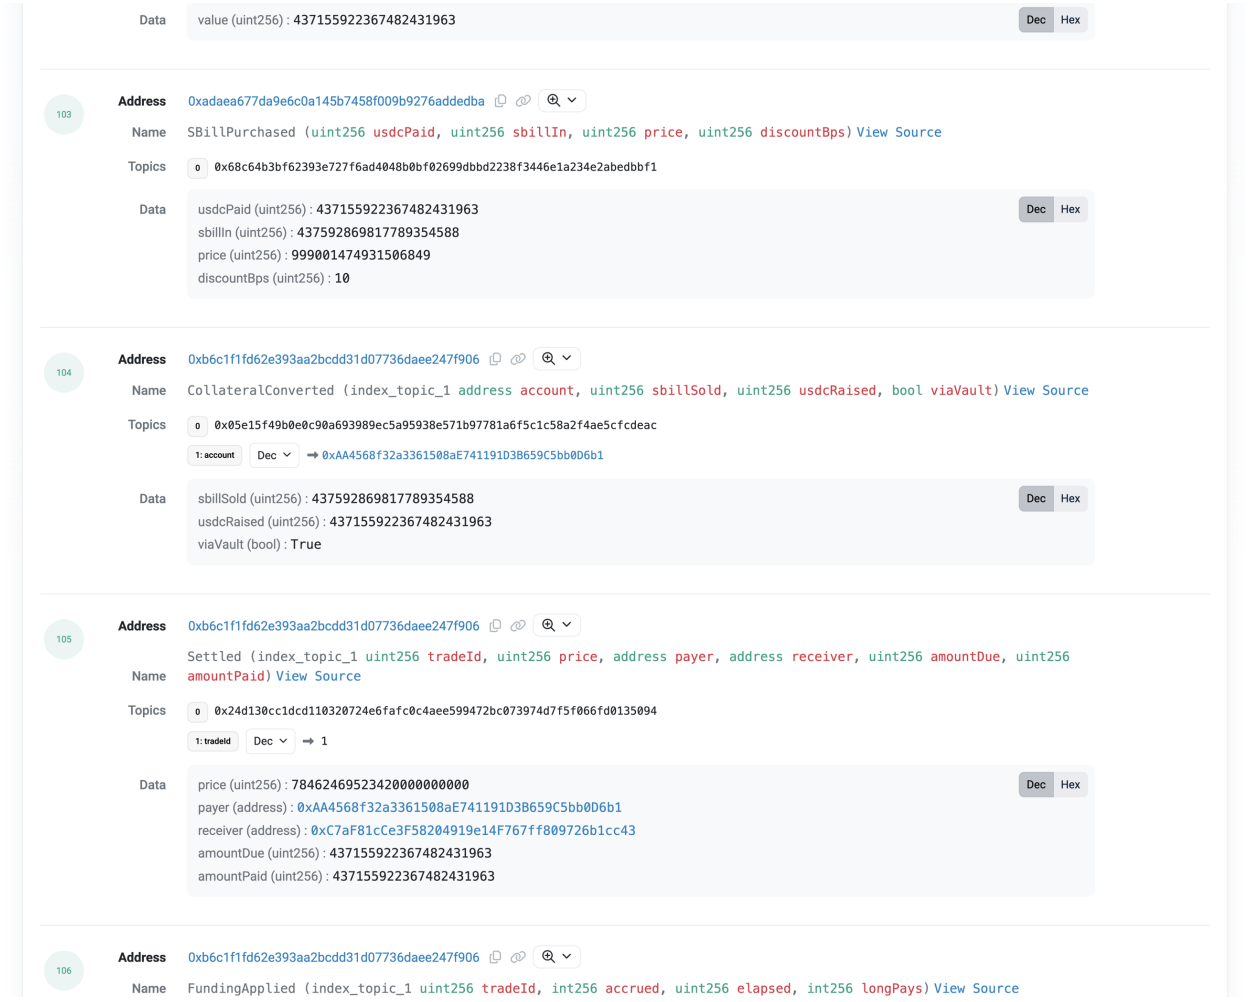

Figure 3: The weekend settlement, event by event — this is the project's central claim. The sBILL `Transfer` moves 437.592869817789354588 from the clearinghouse to the vault; the tUSDC `Transfer` moves 437.155922367482431963 back; and `SBillPurchased` records `price = 999001474931506849` and `discountBps = 10`. The loser held no cash, the T-bill market was shut, and the winner was paid anyway. Every one of those figures appears in the reconciliation table of Appendix B, matched to the wei.

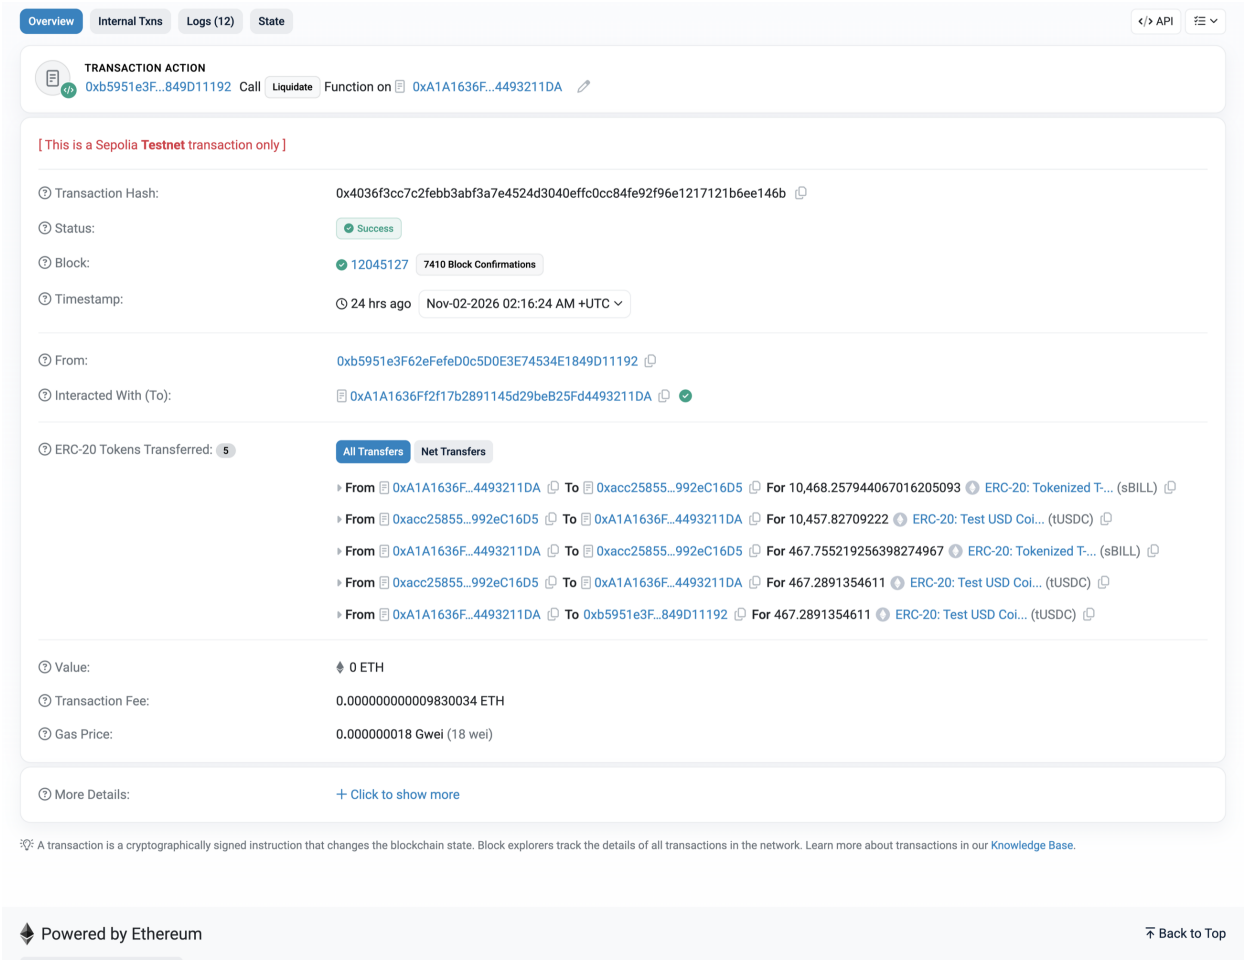

Figure 4: A real liquidation, on the clearly labelled stress set. A `Liquidate` call that succeeded, with five ERC-20 transfers: the losing side's sBILL sold to the vault, cash returned, and **467.2891354611 tUSDC paid to the liquidator** — the 0.5% reward, and the same $467.29 the model predicted in §5.5. **This set's Bitcoin price is a mock;** the Main set uses the real Chainlink feed.

3.8 The settings the contracts actually run with

These come from `config/protocol.json` at deployment. **If any document disagrees with a contract, the contract wins** — and §4.9 reads each of these back off the chain to prove no document does.

Setting	Value	Where it binds
Initial margin	20%	Caps opening leverage at 5×
Maintenance margin	10%	The liquidation trigger
sBILL haircut, market open	1%	sBILL counts at 99% of NAV
sBILL haircut, market closed	3%	sBILL counts at 97% of NAV
sBILL interest	4.00% simple	Accrues on the clock, weekends included
Vault discount	10bp	Owner-adjustable up to a 1% hard cap, only while the market is open
Liquidation reward	0.5% of notional	Paid to whoever calls `liquidate`
Funding cap	0.1% per hour	The largest rate the owner can post
Oldest accepted price	2 hours	Above the feed's roughly 1-hour heartbeat

3.9 The front end

Seven pages, built on Scaffold-ETH 2 with Next.js, wagmi, viem and RainbowKit. It reads the live Sepolia contracts with no wallet connected, and a dropdown switches between the Main, Demo and Stress sets. Every screenshot below was taken from the running application reading Sepolia.

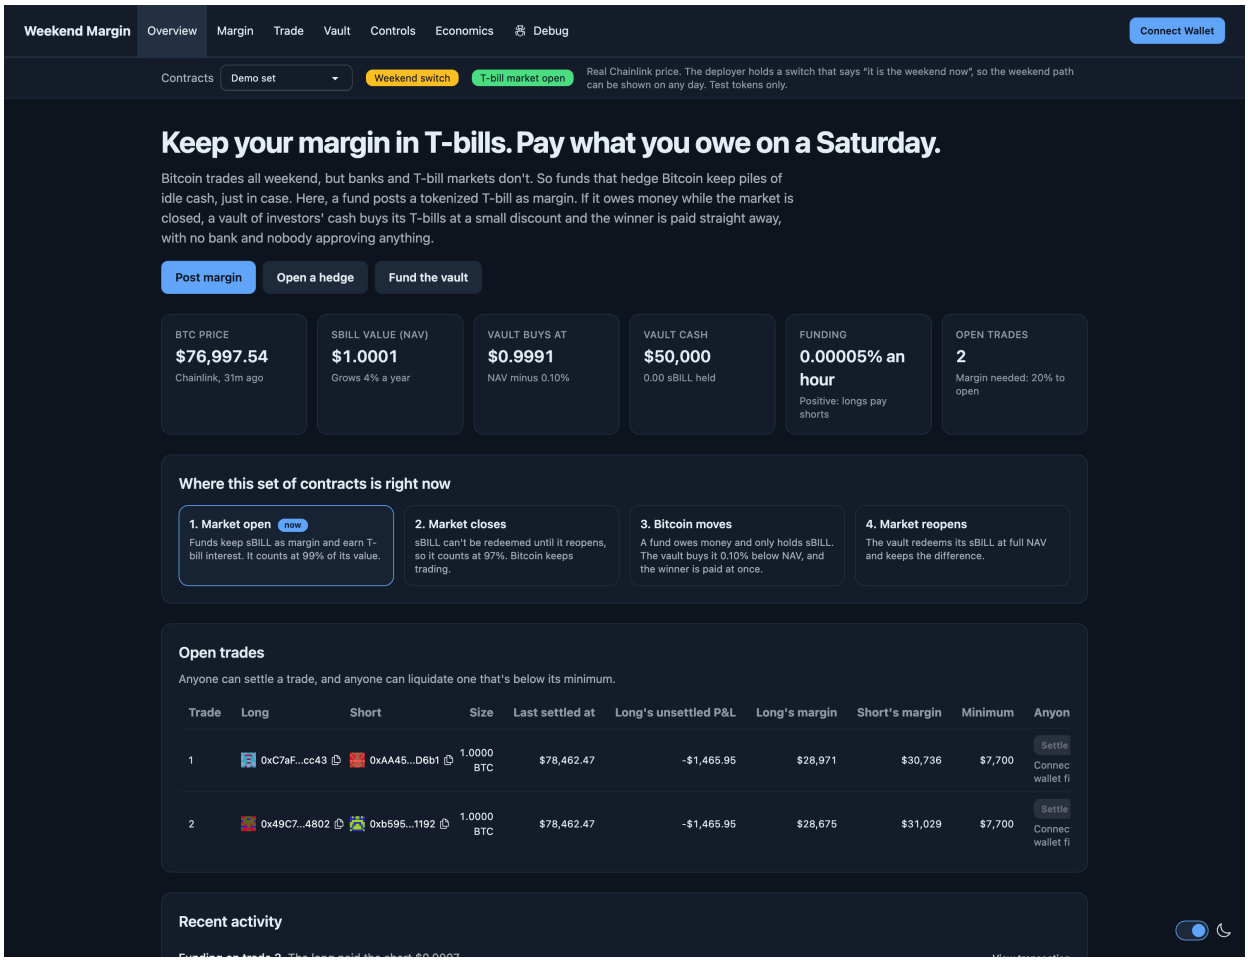

Figure 5: Overview. The live Chainlink price, the sBILL NAV, the vault's cash, the funding rate and the open trades, all read from the deployed contracts. The yellow badge says that the deployer holds the demo weekend switch.

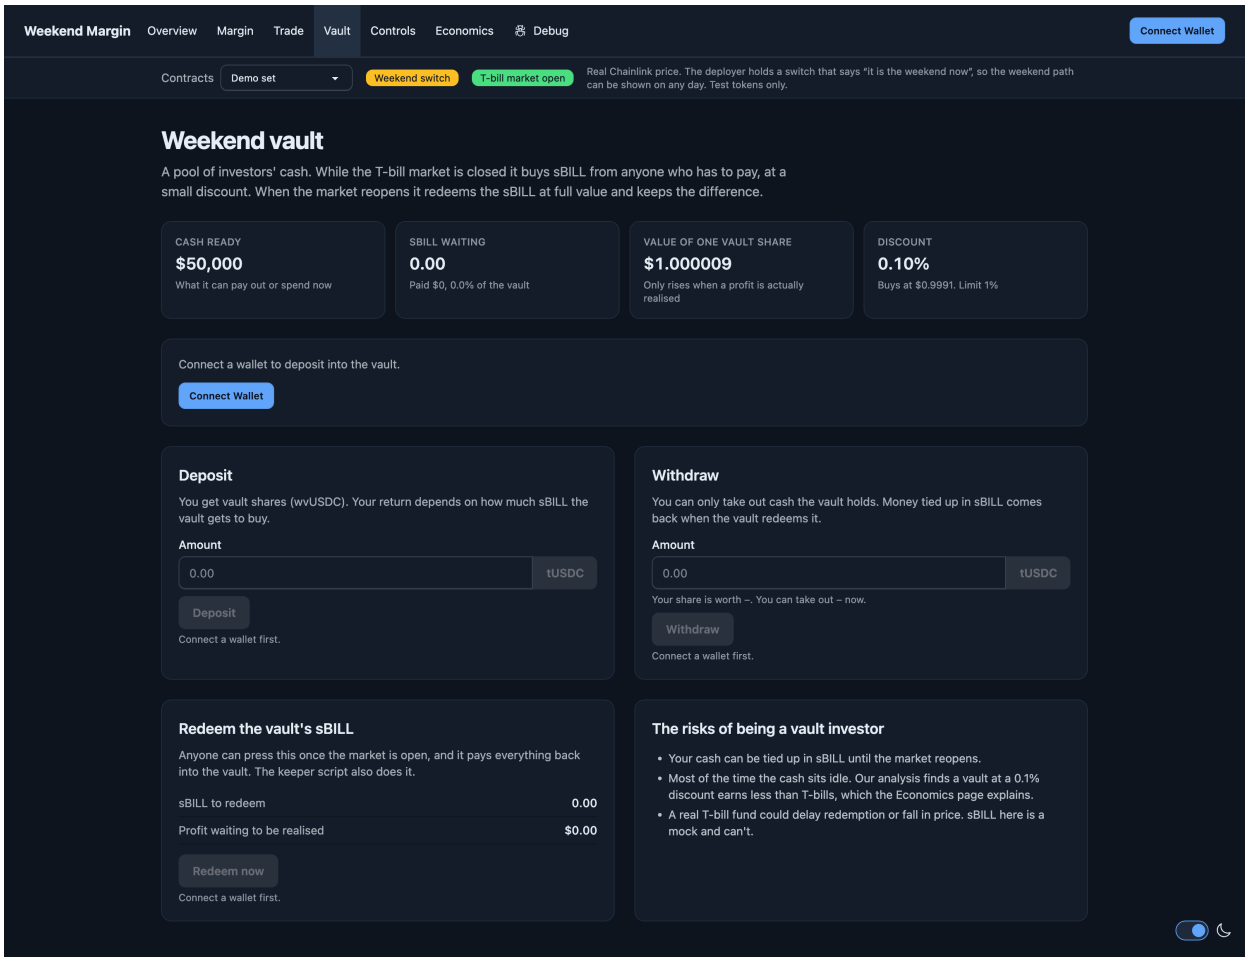

Figure 6: The vault. Cash ready, sBILL waiting for Monday, the share price — which only rises when a profit is actually realised — and the discount with its hard limit. The risks of being a depositor are stated on the page, not buried in a document.

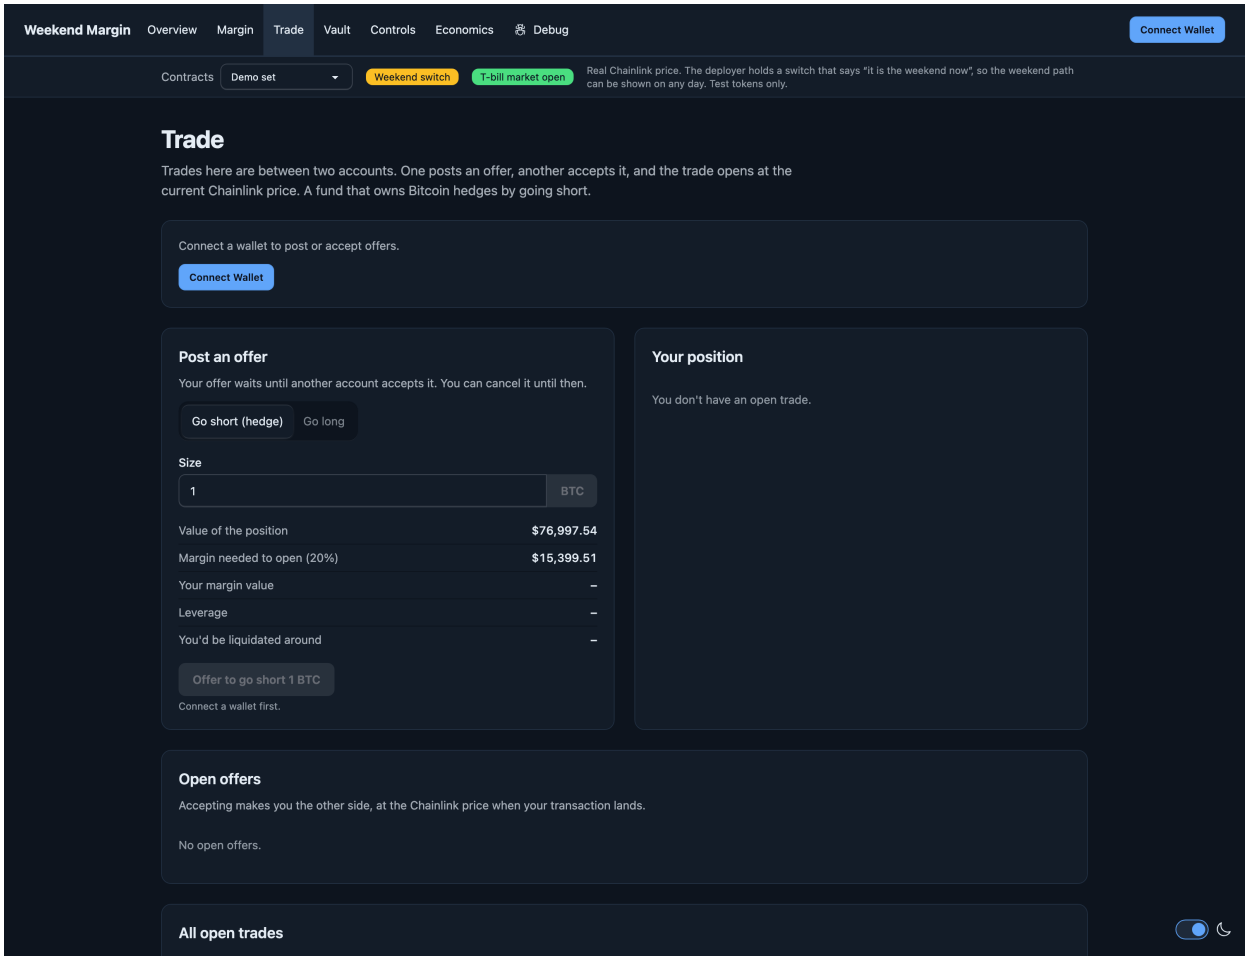

Figure 7: Trading. The liquidation price for *both* sides is computed from the contract's own formula as the inputs change, before anything is signed.

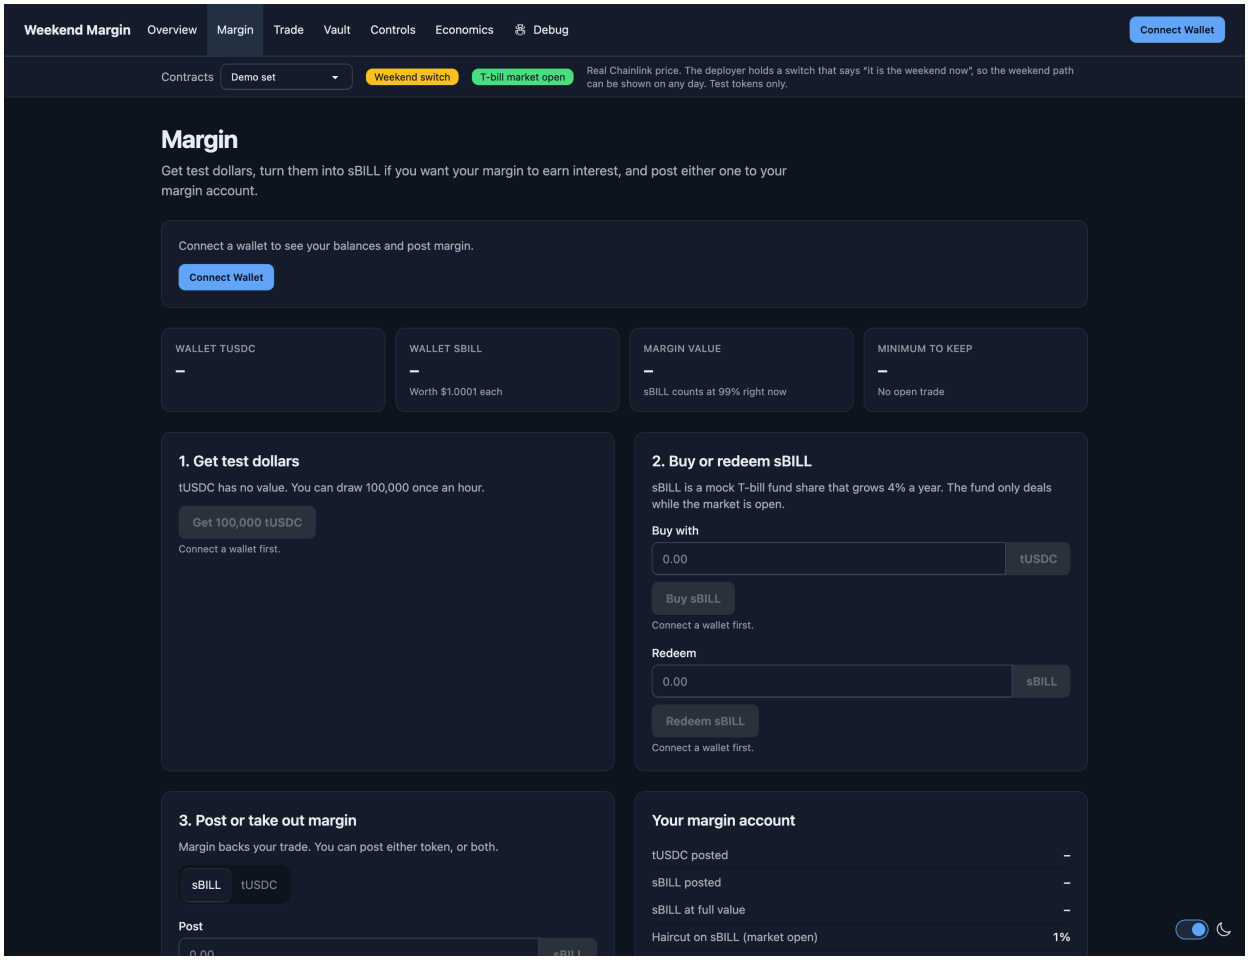

Figure 8: Margin. Deposits and withdrawals in tUSDC and sBILL, with the haircut applied live and account health shown against both margin levels.

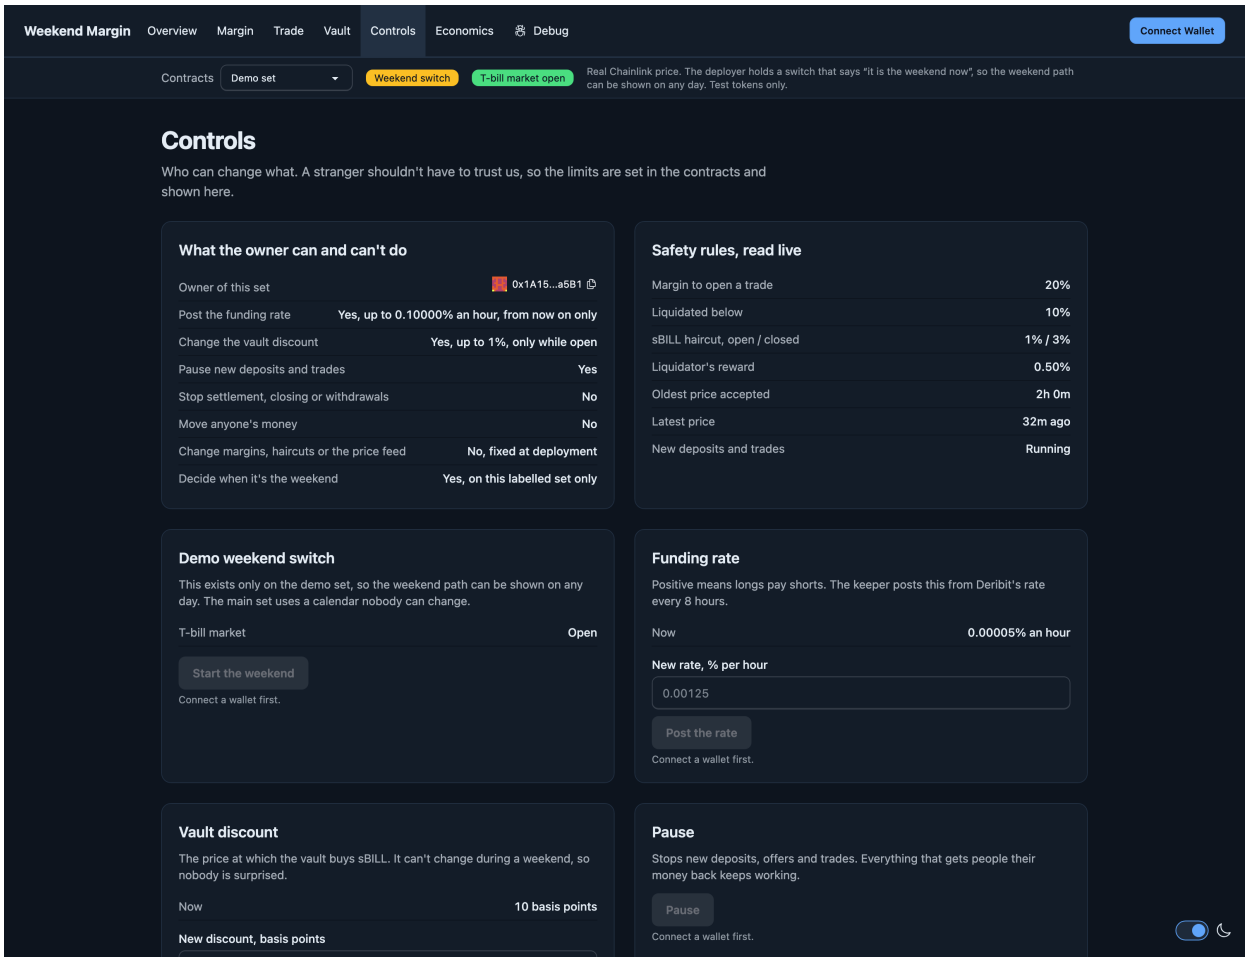

Figure 9: Controls. Every admin power, with its hard limit printed next to it. We put the owner's powers on a page rather than in a footnote, because a stranger should be able to see exactly what we can and cannot do to them.

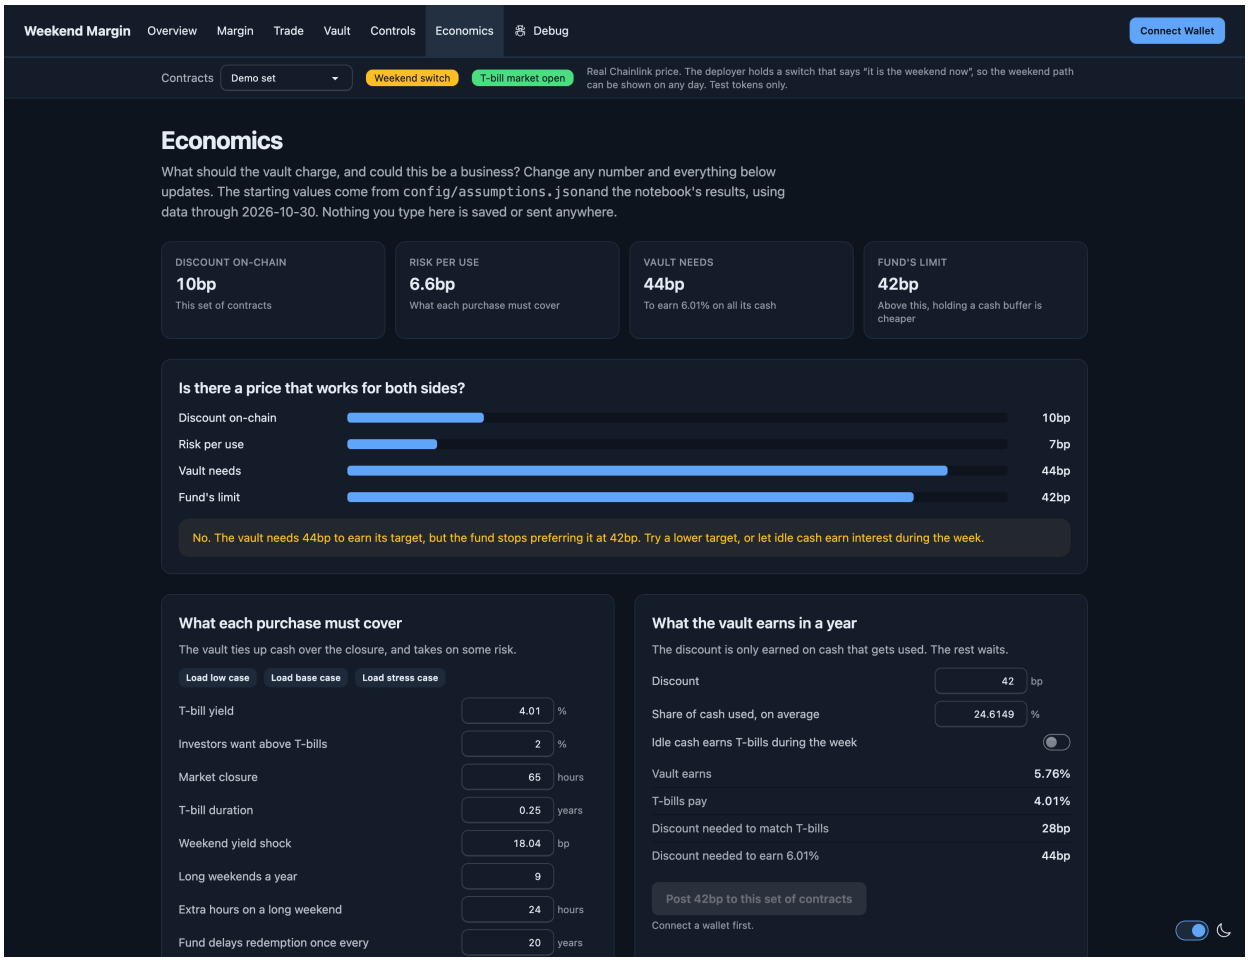

Figure 10: Economics. The whole pricing model from §4.6, live and editable. Change any input and the verdict recomputes — here it correctly reports that at a 2% hurdle the vault needs 44bp while the fund stops paying at 42bp, so no deal exists. The result can be copied straight back into `config/assumptions.json`.

4 Financial analysis

Most of this section comes from `docs/analysis.ipynb`. It runs end to end in about a minute, and **no number is typed into a cell**: every judgement call lives in `config/assumptions.json` and every contract setting in `config/protocol.json`, so a reader who disagrees with us can change one file and rerun. The charts below are written straight to `docs/figures/` by the notebook. Two parts come from elsewhere: the historical stress weekends in §4.8 are written by `docs/stress_weekends.py` from the same cached data with the notebook's conventions, and the break points in §4.10 were derived in the companion document `docs/pricing-and-risk.pdf`. Each section says so.

4.1 Method and data

Series	Source	Coverage	Used for
BTC/USD hourly	Coinbase Exchange, `BTC-USD`	2021-01-01 to 2026-10-30, 51,083 hours (13 filled)	Hedge backtest, closure moves, liquidation, regime stress
BTC perp funding, hourly	Deribit `BTC-PERPETUAL`, `interest_1h`	matched to the above	Funding realism and the hedge's carry
3-month T-bill yield	FRED `DTB3`, daily	2015-01-02 to 2026-10-28, 2,957 obs (3,085 rows, holidays blank)	The yield $y = 4.01\%$ and weekend yield shocks
Live contract reads	Our own Sepolia deployment	28 values at block 12,052,818	Reconciliation (§4.9)

All four series are cached in `docs/data/`, so only the reconciliation section touches the network. The brief names BitMEX for funding data; its API returns HTTP 403 from our US network, so we used Deribit and checked it against itself — the rolling 8-hour sum of `interest_1h` has correlation 0.9997 with Deribit's published `interest_8h`.

The position every number refers to

The reference trade. A fund owns 1 BTC bought at \$77,853.66. It shorts 1 BTC of perp with **\$30,000 of sBILL** as margin — **2.60× leverage**. The counterparty is long 1 BTC with \$30,000 of tUSDC. Holding period 30 days. This is exactly the position the demo opened on Sepolia, so the analysis and the chain describe the same thing.

4.2 Hedged versus unhedged P&L

$$\text{Hedged P\&L} = \underbrace{(P_1 - P_0)}_{\text{spot}} + \underbrace{-(P_{\text{exit}} - P_0)}_{\text{perp}} + \text{funding} + \text{sBILL interest} - \text{vault cost}$$

with funding = rate × average notional (positive means longs pay shorts; the rate is the median month's, 0.32% of notional, about 3.8% a year), interest = sBILL balance × 4% × days/365 on a balance that shrinks by half the loss as sBILL is sold to pay it, and vault cost = 10bp × loss × 65/168, the share of the week the T-bill market is shut.

What the chart says, in three findings.

1. **Between −32% and +26% the result is flat**, at about **\$343 a month** per BTC. The parts, at a +10% move: spot +\$7,785.37, perp −\$7,785.37, funding +\$260.93, sBILL interest +\$85.83, vault cost −\$3.01. The hedge removes the price and leaves the carry, which is the purpose of the hedge.

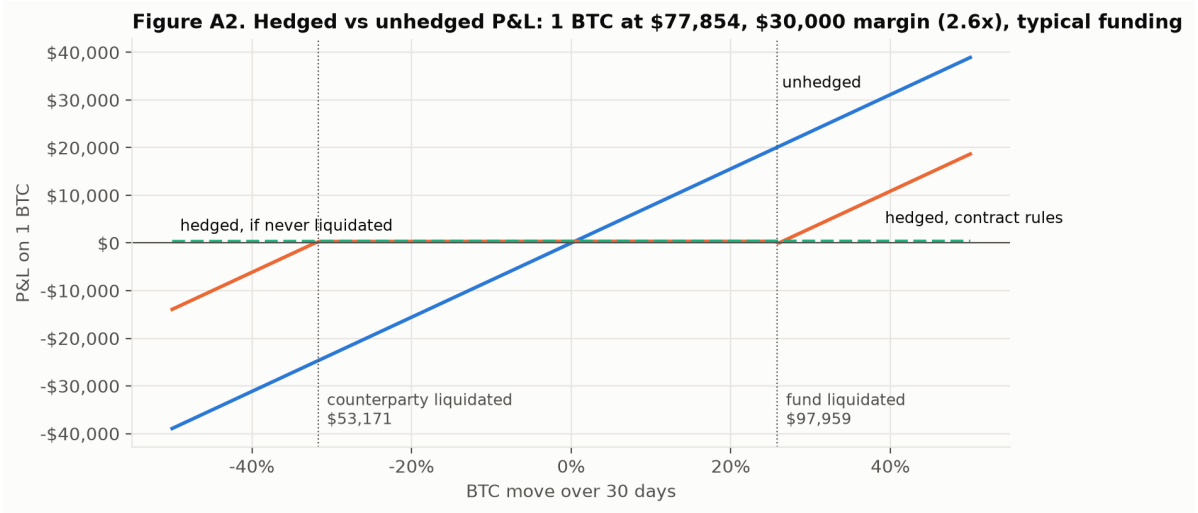

Figure 11: Hedged versus unhedged profit and loss across Bitcoin price scenarios, at the demo's 2.60× leverage. The flat middle is the hedge working. The two cliffs are liquidation.

2. **Outside that range the fund is not hedged at all**, and the apparent upside in the chart is misleading, because the result is path-dependent. If Bitcoin reaches $97,959 the short is liquidated; if it then returns to $77,854, the fund is down **$20,595** on the perp with nothing on the spot side to offset it.

3. **Leverage decides the outcome.** Over 2,099 rolling 30-day windows, hedge effectiveness (1 − hedged variance/unhedged variance) is **97% at 2×, 92% at 2.6×, 60% at 4× and 34% at 4.9×**. Unhedged, those same windows have mean +2.6%, standard deviation 16.9% and a worst case of −43.1%.

Two caveats. The backtest never tops up margin and never re-hedges after a liquidation, which a real fund would do, so it is pessimistic. And ignore the "mean hedged" column when comparing leverage: it *rises* with leverage only because Bitcoin went up over the sample, so a fund liquidated out of its short kept the gain. Read the standard deviation and the worst case.

Unrealized P&L, and where to read it on-chain

The contract exposes unrealized profit and loss directly as `unsettledPnl(account, price)`: the mark-to-market gain on an open position that has not yet been settled in cash. At the moment of the reconciliation read, with Bitcoin at $76,816.82 and trade 1 last settled at $78,462.47 (the keeper's settlement in §5.5):

	Model	Read from the chain
Trade 1, long's unrealized P&L	−$1,646.734697511218543664	−$1,646.734697511218543664
Trade 1, short's unrealized P&L	+$1,646.734697511218543664	+$1,646.734697511218543664
Fund A, margin value after haircut	$29,270.340627669335719301	$29,270.340627669335719301
Fund A, equity	$30,917.075325180554262965	$30,917.075325180554262965
Fund A, maintenance margin	$7,681.682265454000000000	$7,681.682265454000000000
Fund A, initial margin	$15,363.364530908000000000	$15,363.364530908000000000

Unrealized P&L is exactly zero-sum between the two sides, as a bilateral design requires, and the fund's equity of $30,917 sits well above its $7,682 maintenance requirement. The **strategy** this implies is stated in §7.2.

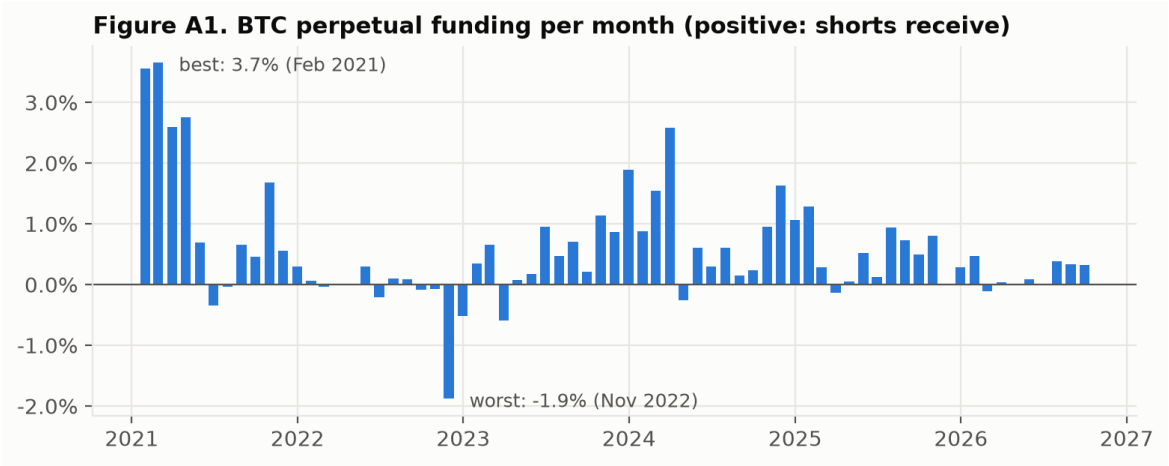

Figure 12: Monthly funding on a 1 BTC perpetual, from Deribit hourly rates. Positive means the short is paid.

4.3 Funding

Measurement	Result
Mean funding rate over the sample	**6.6% a year**, paid by longs to shorts
Months in which the short *pays*	**20%**
Worst month for a short	−1.9%, November 2022
Largest hourly rate ever observed	**0.0609%** per hour
The contract's hard cap	0.1% per hour — **never reached in 51,083 hours of data**

So funding is a *real* risk and a *small* one next to price. A short hedger is paid about two thirds of the time, and the contract's cap sits roughly 1.6× above anything the market has produced in six years — tight enough to constrain an owner, loose enough never to block a legitimate rate.

4.4 The liquidation price

With D the deposit, $h = 1 - \text{haircut}$ (so $h = 1$ for tUSDC), $m = 10\%$ the maintenance margin, and P_0 the entry price, an account is liquidated when what remains after settlement and the haircut falls below m times the notional:

$$\text{Short:}\quad h\,(D - (P - P_0)) = mP \implies P_{\text{liq}} = \frac{h\,(D + P_0)}{m + h} \qquad \text{Long:}\quad P_{\text{liq}} = \frac{h\,(P_0 - D)}{h - m}$$

Position	Liquidated at	BTC move	Note
Fund's short, 2.60×, sBILL margin	$97,959	+25.8%	The demo's actual position
Counterparty's long, 2.60×, tUSDC	$53,171	−31.7%	

Margin posted as	Max leverage	Why
tUSDC margin	5.00×	The 20% initial margin
sBILL, market open (1% haircut)	4.95×	
sBILL, market closed (3% haircut)	4.85×	
10×	**cannot open**	It would already be below maintenance at entry

Two results worth keeping. **The weekend haircut barely matters** — switching from 1% to 3% moves the liquidation price by about $185 on a figure near $98,000, or 0.19%, and costs a tenth of a turn of leverage. **The vault discount matters even less**: $18 at the demo's size. Both buffers are close to free, which is the strongest argument for keeping them.

The finding that changed how we think about this product. The 20% initial margin is about right for *trading* and too loose for a month-long *hedge*. With no top-ups, a position at 4.9× has roughly a 20% chance of liquidation within a week and about 55% within 30 days; at the demo's 2.6× it is 14% over 30 days. A liquidated hedge is worse than no hedge, because the fund discovers it is naked at exactly the moment it most needed cover. A hedger should sit near 2–2.6× or plan to add margin.

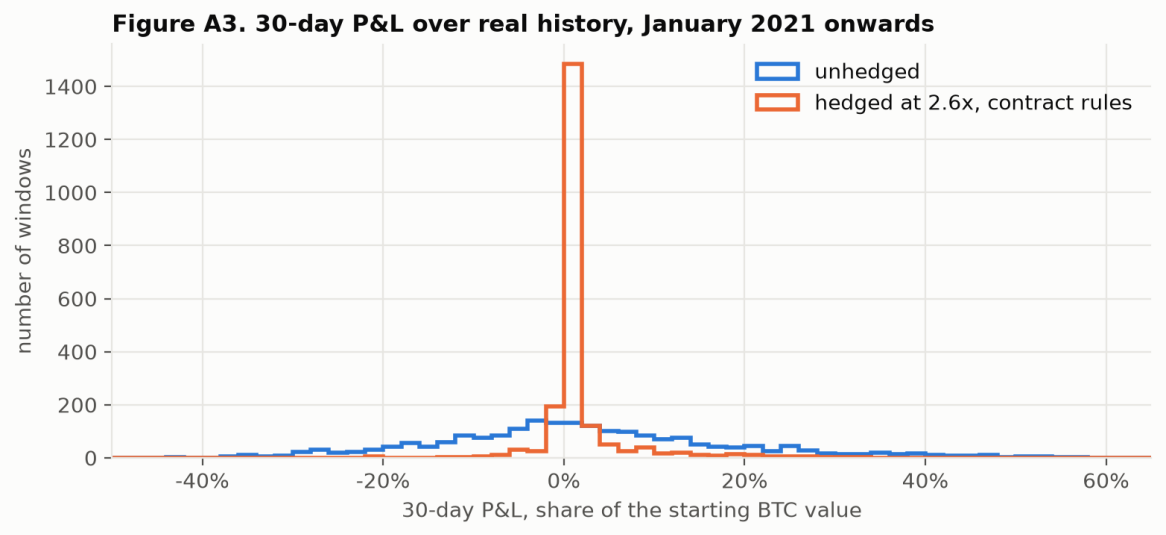

Figure 13: Rolling 30-day backtest across 2,099 windows: hedged versus unhedged outcomes by leverage.

4.5 Is a weekend actually more dangerous?

We expected yes. The data says no.

	Inside closures	Outside closures
Hourly volatility	**0.523%**	**0.680%**

65-hour closure, 304 weekends since 2021		
99th-percentile adverse excursion within a closure, against a short (price up)		+13.47%
99th-percentile adverse excursion within a closure, against a long (price down)		−14.42%
99th-percentile Friday-to-Monday net move, up / down		+11.10% / −12.97%
Worst closure in the sample		20.41%
Fitted growth of volatility with horizon (exponent)	0.493	(square-root rule says 0.5)
Weekend-to-overnight volatility ratio	1.66	(square-root rule predicts 1.96)

An adverse excursion is the largest loss reached at any hourly settlement during the closure, which is what settlement actually charges and what the vault has to fund. The Friday-to-Monday net move is smaller because prices partly recover before Monday. The vault sizing below uses the excursion.

Three consequences.

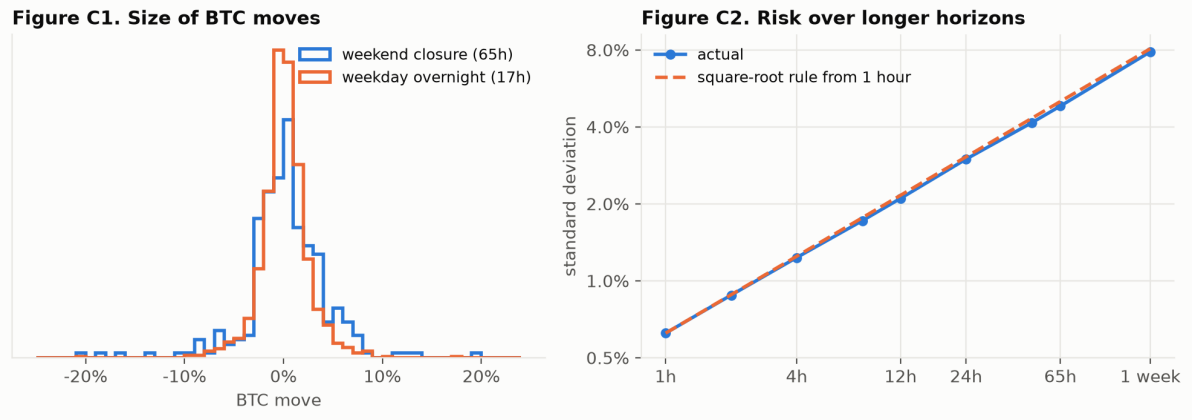

Figure 14: Weekend closures against matched weekday windows. Per hour, closures are calmer; they are dangerous because they are long and because the collateral cannot be sold.

- **The weekend problem is a plumbing problem, not a volatility problem.** Bitcoin does not misbehave at weekends. The T-bill market being shut is the entire issue, which is why a vault, rather than a larger margin requirement, is the right response.
- **The square-root rule overstates the tail.** Over every 65-hour window in the sample, the 99th percentile of the absolute move is 15.9%, against 19.3% if the one-hour figure is scaled by the square root of time. Using the rule would have made us hold about 20% more vault capital than the data requires.
- **Maintenance margin holds up well.** A 10% margin would have been breached by a single-hour move in only **2 of 51,083 hours**, and by a two-hour move in 4 — all in January and May 2021. Two hours is the relevant window because it is the oldest price the contract accepts. In those rare cases an account sitting exactly at maintenance could underpay the winner, because there is no insurance fund.

The sample is small where it matters most: 304 weekends means a 99% figure rests on about three observations. The 90% bootstrap interval is 7.7%–13.9% for rises and 8.7%–18.3% for falls, so read these as ranges, not points.

4.6 What should the vault charge?

This is the question the proposal feedback asked. The answer has two parts that give very different numbers, and the distinction between them is the most useful result in our analysis.

Part 1 — the cost of each use

Per dollar the vault actually deploys over a closure of h hours:

$$\underbrace{\frac{(y+\pi)h}{8760}}_{\text{gross carry}} - \underbrace{\frac{yh}{8760}}_{\text{the sBILL keeps accruing}} + \underbrace{D \cdot \Delta y}_{\text{T-bill price risk}} + \underbrace{p_\ell \frac{(y+\pi)h_{\text{extra}}}{8760}}_{\text{long-weekend risk}} = \text{required discount}$$

with y the T-bill yield, π the hurdle premium vault depositors require above T-bills, D the collateral's duration, Δy the weekend yield shock, and p_ℓ the chance of a Monday holiday. Note that the first two terms largely cancel: the vault's capital must earn $y + \pi$, but the sBILL it is holding is itself earning y, so only the premium has to come out of the discount. The notebook adds one more small term: an allowance of about 0.3bp for a redemption gate (one gate in twenty years, costing 3%). The companion document omits it, which is why its base case is 6.3bp where the notebook's, used below, is 6.6bp.

Δy is an **empirical percentile, not a standard deviation**, and that choice is deliberate. Weekend yield moves are far from normal: a normal distribution expects 0.04 weekends beyond 4σ in a sample this size and we observe nine, and June 2022 is an 8.4σ move (both computed in `docs/pricing-and-risk.pdf`). We read the quantile straight off 597 observed weekends instead.

Weekend yield move, 597 weekends since 2015	**Yield**	**Price impact at $D = 0.25$**
Median	2bp	0.50bp
95th percentile	10bp	2.50bp
99th percentile	18.04bp	4.51bp
Largest ever, 2022-06-10	35bp	8.75bp

Case	**Hurdle**	**Duration**	**Shock**	**Discount required**
Low	4.01%	1 month	10bp	1.3bp
Base	6.01%	3 months	18bp	**6.6bp**
Stress	9.01%	3 months	35bp	13.2bp

The contract charges 10bp, which is 1.5× the base requirement. The largest single component is T-bill *price* risk — 4.51 of the 6.6bp. The most important thing our fee prices is the risk that interest rates move while the vault holds the paper.

Part 2 — the cost of cash that waits, which is where 10bp fails

The vault must hold enough cash for a bad weekend. Most weekends use almost none of it. Measuring each weekend's draw from the real hourly price path — the *largest* loss reached at any hourly settlement, not the final one, because settlement is continuous:

A hedging fund sells, per weekend, on average	**2.50% of notional**
median	1.80%
largest	19.9%
Cash needed to cover 99% of weekends — shorts only	13.47% of notional
Cash needed to cover 99% of weekends — longs only	14.42% of notional
Cash needed, one pool serving both directions	**19.69% of notional**
pooling saves **29%** of the capital, the largest single efficiency in the design	
Average utilisation at that sizing — shorts only	18.29%
Average utilisation at that sizing — both directions	24.61%

The main finding, which goes against our own deployed setting. At the deployed **10bp the vault earns 1.2–1.7% a year against 4.01% on T-bills**. It loses to its own alternative. The cause is *not* the weekend: 10bp covers the 6.6bp cost of every use comfortably. The cause is that three quarters of the vault's capital is idle waiting for a weekend that mostly does not need it. A real vault needs **28bp to match T-bills and 44bp to earn T-bills + 2%**, serving both directions from one pool.

Three things would fix it, and they are the design roadmap:

1. **Raise the discount.** Serving shorts only: 39bp to match T-bills, 60bp for T-bills + 2%. Serving both directions: 28bp and 44bp.

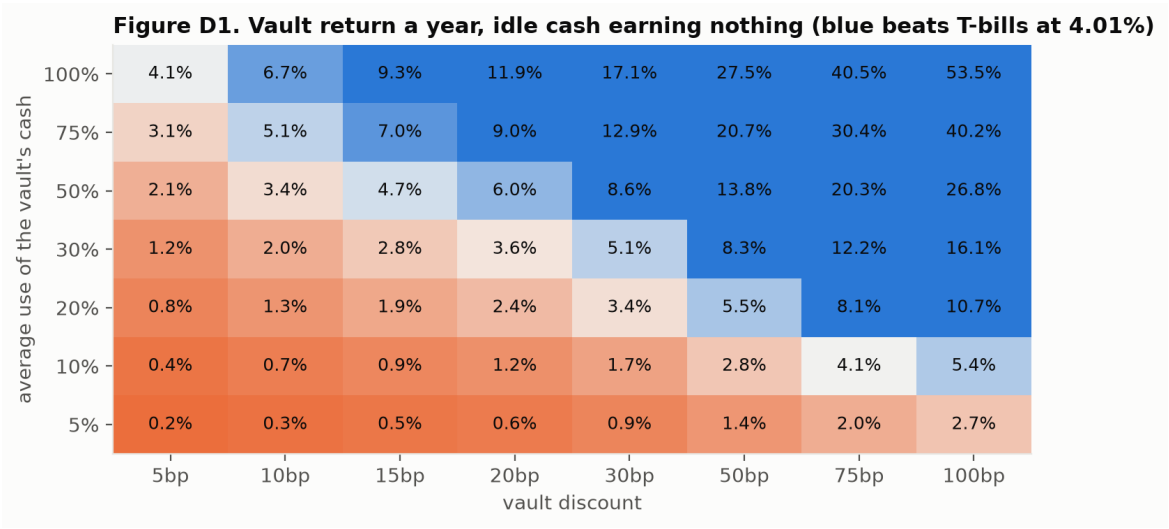

Figure 15: What the vault actually earns, per year, as a function of the discount it charges — against the 4.01% it could have earned simply holding T-bills.

2. **Serve both directions from one pool** — already true in our design, and worth 29% of the capital.
3. **Sweep idle cash into T-bills on business days.** With both directions plus a sweep the vault needs only **9bp** to match T-bills and 25bp for T-bills + 2%. Our contracts do not do this; it is the single highest-value extension.

What we did about it. We left 10bp deployed, because the contracts are frozen, and we report the result as it is. The discount is owner-adjustable up to 1% without a redeploy, so the fix is one transaction away, and the Economics page can post it.

4.7 Is the fund better off? The price band

The other side of the trade. Take a $1,000,000 hedge at the demo's leverage ($385,338 of margin) and compare four ways to hold that margin for a year:

1. All cash	income $= 0$
2. T-bills + a cash buffer	income $= y\,(M - \text{buffer})$, buffer = 99% weekend move × notional
3. T-bills, sold every Friday	income $= y\,(M - \text{buffer} \times 65/168)$, and someone must trade every week
4. **All T-bills + our vault**	income $= y\,M -$ discount × sBILL sold

On a $1m hedge, $385,338 of margin	**Return on margin**	**Income**
All cash	0.00%	$0
T-bills + cash buffer	2.61%	$10,050
All T-bills + the vault, at 10bp	**3.67%**	**$14,150**

The fund pays about $1,300 a year in discounts (it routes roughly $1,301,320 of sBILL through the vault annually) to earn about $15,450 of T-bill interest. That is the product in one line.

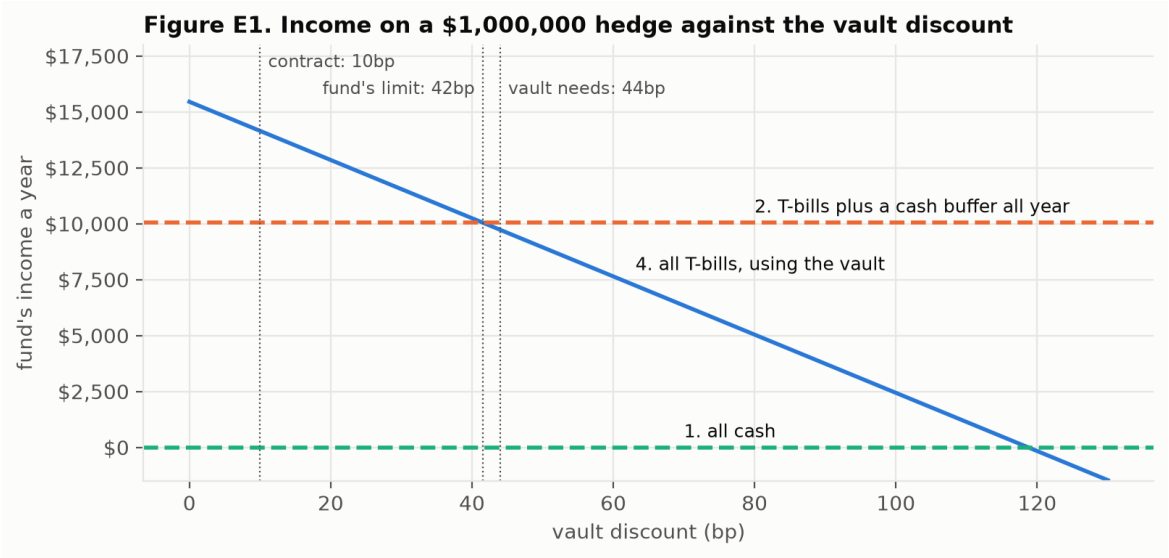

Figure 16: The fund's income against the discount charged, with the vault's break-even lines. The two constraints almost touch — which is the real finding.

Constraint	Discount (bp)
Vault must earn at least this to match T-bills (both directions, one pool)	28
Vault must earn at least this for T-bills + 2%	44
Fund will pay at most this, against holding a cash buffer	**42**
Fund will pay at most this, against selling T-bills every Friday	16
Fund will pay at most this, against holding everything in cash	119

A workable price exists between 28 and 42bp — and only against the cash-buffer alternative. Against a fund disciplined enough to sell T-bills every Friday there is no overlap at all. This is a narrow business, and we say so. It also requires rates: at 2021's 0.05%, a user of this product would have *lost* about $2,222 a year on a $1m hedge.

4.8 Stress: what history would have done to us

For each crisis we take the worst 65-hour closure in the surrounding window, measured as the adverse excursion from Friday 4pm ET on settled hourly closes. Excursion, not the Friday-to-Monday net move, because settlement is hourly: the loser pays as the price goes against it, and a later recovery does not hand back collateral already sold.

The table is written by `docs/stress_weekends.py` from the cached Coinbase series, with the notebook's conventions (hourly settlement at the candle open, Friday 4pm New York time, 65 hours), so it agrees with the notebook's table of the busiest weekends (Section C). Each row is the worst closure within three weeks of the event, and the script checks that. The companion document's version of this table uses a slightly different convention (hourly closes from Friday 20:00 UTC) and takes each named event's own weekend, so its figures differ by small amounts and, for October 2025, it shows the 24th where this rule selects the 10th, the weekend of the figure below. Its conclusions hold under both; where the two differ, this table is the one to cite.

Regime	Weekend	BTC Fri 4pm	Excursion	Loser	Sold per $1m	% of 95th-pct vault
Yen carry unwind	2024-08-02	$62,558	20.41%	long	$204,111	**207%**
June 2022 CPI shock	2022-06-10	$28,951	18.33%	long	$183,343	**186%**
SVB / USDC depeg	2023-03-10	$19,975	13.51%	short	$135,125	**137%**
May 2021 mining ban	2021-05-14	$50,165	14.44%	long	$144,379	**147%**
LUNA/UST collapse	2022-05-06	$35,996	8.86%	long	$88,640	90%
Oct 2025 liquidations	2025-10-10	$116,673	5.92%	long	$59,211	60%
FTX collapse	2022-11-11	$16,573	4.44%	long	$44,435	45%
Typical weekend	—	—	3.95%	—	$39,472	40%

Read that last column carefully, because it is the single most important risk number in this project. A vault sized at the 95th percentile of that excursion distribution holds $98,461 per $1m of notional, and **four of the seven crises exceed it**. When the vault empties, `settle()` reverts and settlement waits for Monday — a safe failure, but a failure, and exactly in the weekends the product exists for.

The binding constraint is capital, not price. In every one of those seven weekends the 10bp fee was comfortable; in four of them the *cash* was not. That moves the open design question from "is 10bp enough?" — which we can now answer yes, for each use — to "how much capital stands behind it?", which is where the remaining work belongs. We size at the 99th percentile for this reason, and we would go higher.

Does the position survive? By the same script, at the demo's 2.6× nothing is liquidated in any of the seven regimes. At 4× the June 2022 and yen-unwind longs go, and the SVB short goes. At the 4.85× maximum the 2021 mining-ban long goes too. **The demo is safe because it is conservatively levered, not because the parameters are strong**, which the Sepolia run alone would not show.

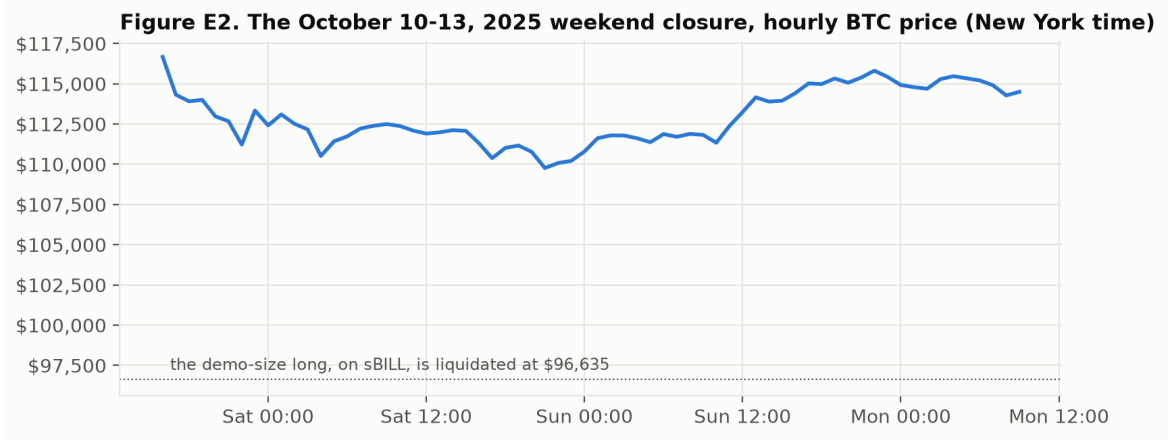

Figure 17: October 10–13, 2025, the most recent real stress weekend. On Coinbase hourly data Bitcoin fell 5.9% from the Friday 4pm ET price of $116,673 (8.3% at the lowest trade). The demo's long side would have sold $6,908–$9,673 to the vault — at most 19% of the $50,000 demo vault — and would not have been liquidated. Other assets and other venues fell much further that weekend, which BTC-only, single-exchange data cannot show.

4.9 Reconciling the model with the chain

We compared 28 numbers the model computes with what the deployed contracts report on Sepolia. Every one agrees to the wei.

Contracts do whole-number arithmetic with 18 decimals, so the notebook uses Python integers and rounds exactly as the contract rounds. A "match" means equal to the last of 18 decimal places, and the cell raises an error rather than reporting a near miss.

Read at block 12,052,818, 2026-11-03 04:09 UTC	Compared	Result
Settlements (amount due and funding)	8	all match
Vault purchase (price and sBILL taken)	2	all match
Vault redemption (cash received and profit)	2	all match
sBILL redeemed with the fund (tUSDC paid)	1	match
sBILL subscriptions (NAV and shares minted)	4	all match
Live state (NAV, purchase price, funding total)	4	all match
Account health (collateral, equity, both margin levels)	4	all match
Unrealized P&L, both sides of trade 1	2	all match
Liquidation reward, stress set	1	match
Total	**28**	**28 match, difference 0**

Two of these deserve a note. The **funding check** rebuilds the contract's running total from the posted rates alone, so it would catch any error in how a rate change is applied — it is a test of the fix in §2, not just of a number. And the **liquidation check** does not only compare the reward: `demoLiquidation.ts` computes the liquidation price from the formula in §4.4, then shows the contract refusing at 0.1% below it and accepting at 0.1% above it.

The full table is in `docs/data/sepolia_reconciliation.csv` and reproduced in Appendix B. On a tougher local rehearsal — repeated demos, rate changes, a discount change and a liquidation — all 51 comparisons matched too.

4.10 Where each assumption breaks

Stating assumptions is necessary but not sufficient. The useful exercise is to solve each one for the value at which our conclusion stops holding, and then ask whether history has already reached it. The thresholds below were derived in `docs/pricing-and-risk.pdf` from the four-term decomposition of §4.6, without the 0.3bp gate allowance; the notebook's sensitivity grids (Section C) show the same pattern.

Input	Base	Breaks above	Headroom	Reached in history?
Weekend yield shock	18bp	**32.9bp**	1.8×	**Yes — 35bp, June 2022**
Collateral duration	0.25 yr	**0.456 yr**	1.8×	Immediately, on 6-month paper
Closure length	65 h	228 h	2.0×	No. Longest ever is 113 h (Thanksgiving)
Hurdle premium	2.0%	6.7%	3.4×	Not observable

Two of the four matter and two do not. Closure length and the hurdle premium have two to three times the headroom they need, so a reader can argue about them freely without changing a conclusion. The yield shock has already been breached once. And **duration is the tightest**

assumption in the model — and the only one that is about our own collateral rather than about the world, which makes it the one we can actually do something about.

Collateral	Loses money above	Worst ever	Verdict
3-month bill (our assumption)	51.9bp	35bp	1.5× headroom
6-month bill	26.0bp	35bp	**Has already happened**
1-year note	13.0bp	35bp	**Happens regularly** — the 99th percentile is already 18bp

The design implication is concrete and belongs in the contract rather than in a spreadsheet: **the vault should accept only short-dated collateral, and that limit should be enforced, not assumed.**

What "breaks" means. Two thresholds are easy to collapse into one and should not be. Missing the hurdle (depositors earn less than they required) happens at 32.9bp and *has* occurred once, June 2022. Losing principal (the ERC-4626 share price actually falls) needs 51.9bp and has never occurred. On $100,000 routed through the vault, June 2022 would have left it $5.19 short of what it promised, having still made $42.25. A small shortfall, not a loss of principal.

4.11 Three risks the fee does not properly price

Three risks are left out of the fee, or covered only by a nominal allowance, so that a reader can see exactly what it covers and what it does not.

1. **Our own token cannot express the risk that dominates its fee.** `SBill.nav()` grows purely on the clock, so rates cannot move it. T-bill price risk is 4.51 of the 6.6bp required discount — **72% of the fee** — and it is a risk our deployment *structurally cannot experience*. The 35bp spike of June 2022 would be invisible to us. We priced the asset the design calls for rather than the mock standing in for it, which is the right way round, but it means the largest component of our fee is one no unit test and no Sepolia transaction can exercise.
2. **Redemption gates: a nominal allowance, not an estimate.** A tokenized fund can suspend redemptions, and our own `SBill` has the same shape of failure — `redeem()` pays from a reserve funded once after deployment. The notebook's base case allows about 0.3bp for this (one gate in twenty years, costing 3%). The sector is about two years old and has never been stressed, so that frequency is a judgement rather than an estimate. The more useful statement is the threshold: **the fee stops clearing its hurdle if gates reach about one weekend in eighty**, roughly once every eighteen months.
3. **The stablecoin leg, which is the largest exposure in the whole system.** The model prices 4.51bp of risk on paper the vault holds for 65 hours, and **zero** on the stablecoin it holds permanently. In March 2023 USDC traded at $0.87 — **1,300bp**, more than two hundred times our entire risk budget, or 89 years of fee revenue on a $1m book. It is also wrong-way: the vault holds the most cash during a crisis, and a crisis is when stablecoins depeg. The SVB weekend appears twice in this report for that reason — third-largest draw in §4.8, and largest unpriced loss here. Circle's own stated trigger was that its wires had not settled before the weekend, which is the identical mechanism we built this system to address.

This is not a charge any fee absorbs; it is a position limit. A production version would cap the vault's idle balance, hold part of it in a second stablecoin, or accept the exposure explicitly rather than silently.

4.12 What we would change in the model

1. Cap collateral duration in the contract. The tightest assumption, currently unenforced.
2. Cap or reserve against the stablecoin leg.
3. Size the vault above the 95th percentile. Four of seven historical crises exhaust it.
4. Emit signed profit and loss from `redeemInventory()` — see §5.2.
5. Promote five judgement parameters out of notebook function defaults and into the settings cell, so a reader can disagree with them without reading code.

5 Testing, security and gas

5.1 The test suite

One command, `yarn test`. **37 tests, all passing**, in about a second, across thirteen groups. **25 of them expect a revert** — we tested what the contracts refuse at least as hard as what they allow.

Group	What it pins down
`MarketCalendar` (3)	Closed for exactly 65 hours, closes exactly at Friday 21:00 UTC, and reports itself as the real calendar rather than the demo one
`DemoCalendar` (1)	Only the operator can switch the weekend
`SBill` (2)	Accrues 4% a year; **refuses to issue or redeem on a non-business day**
`WeekendVault` (4)	Only the owner changes the discount, within the hard limit, while the market is open; prices correctly after a change; refuses a starting discount above the cap; only sells cash to the clearinghouse, and the link cannot be changed twice
Weekend margin call (4)	**The headline path**: sells sBILL to the vault on Saturday, the vault profits on Monday; caps withdrawals while sBILL waits; refuses to redeem before the market reopens; reverts when the vault is short of cash
Weekday settlement (2)	Redeems with the fund at full NAV instead of using the vault
Price feed (3)	Rejects a price over 2 hours old, accepts one just under, rejects zero or negative
Margin rules (4)	Refuses an oversized offer; refuses a withdrawal that breaks margin; stops self-dealing; closes cleanly
Funding (4)	Charges hourly at the posted rate; **applies a new rate only from the moment it is posted**; adds up across a change; caps the rate and restricts it to the owner
Liquidation (5)	Pays the liquidator 0.5%; works through the vault at a weekend; **underpays the winner rather than reverting** when a deposit runs out; **matches the liquidation-price formula**; refuses a healthy trade
Pause (1)	Stops new deposits and offers, but **never** settlement, withdrawals or closing
Randomised invariant (3)	Seeds 7, 42 and 2026: thousands of random settlements, and **no tUSDC or sBILL is ever created or destroyed**
Demo deployment (1)	A Thursday settlement routes through the vault once the operator flips the switch

The three randomised runs are the ones we trust most. They do not check a number we chose; they check that the books balance after arbitrary sequences of settlement, which is the property a clearinghouse actually has to have.

5.2 Slither

Slither 0.11.6, run against every contract with the same compiler as the deployment. **26 findings on our own code. We fixed 4 and explain all 22 of the others, one by one, in `docs/slither.md`. None is an exploitable bug.**

Severity	Before		After
High	1	1	(a false positive, below)
Medium	9		8
Low	14		12
Informational	2		1

What we fixed

Finding	Where	The fix
`uninitialized-local` (Medium)	`liquidate`: `address account` declared empty and set in a branch	Rewrote so the check comes first and the variable is set once
`shadowing-local` (Low) ×2	`maxWithdraw`, `maxRedeem`: a parameter named `owner` hid `owner()`	Renamed it `holder`
`unindexed-event-address` (Info)	`ClearinghouseSet`	Made the address `indexed`

We also reduced a `reentrancy-no-eth` finding by moving the trade's price, funding total and timestamp updates *before* any token movement in `_settle`.

What we looked at and kept, with the reason

Finding	Where	Why it is fine
`weak-prng` (**High**)	`MarketCalendar.secondsIntoWeek`	**False positive.** Slither sees `%` applied to a timestamp and assumes someone is generating randomness. This is arithmetic to find the time of week. No randomness exists anywhere in the project
`reentrancy-no-eth` (Medium) ×4	`closeTrade`, `liquidate`, `_settle`, `_collect`	Every entry point is `nonReentrant`; the callees are our own contracts, fixed at deployment; and the ERC-20s here have no transfer hooks, so no outside code can run mid-call. **We note the limit of that reasoning: against a production issuer whose token may have hooks or a blocklist, this needs revisiting**
`incorrect-equality` (Medium) ×3	`shares == 0`, `amountDue == 0`, `tradeId == 0`	Each is a "nothing to do" check. Sending the vault one wei of sBILL only means it gets redeemed; a trade ID cannot be influenced from outside
`unused-return` (Medium)	`_price`	Deliberate. `latestRoundData` returns five values and we check four. `startedAt` adds nothing once `updatedAt` is checked
`missing-zero-check` (Low)	`setClearinghouse`	Harmless: a zero address leaves the link unset and the owner can call again. It can never be changed once set
`reentrancy-events` (Low)	`redeemInventory`	The event is emitted after a call to sBILL, our own contract, and the inventory cost is already zeroed before that call
`timestamp` (Low) ×10	NAV, funding, calendar, staleness, faucet	The system depends on the clock by design. A validator can move a block's time a few seconds; at 4% a year that is a fraction of a cent
`solc-version` (Info)	`pragma ^0.8.20`	The pragma permits older compilers, but the project compiles with exactly 0.8.30, pinned in `hardhat.config.ts`

What the scanner could not find

This part matters most. A scanner looks for known code patterns; it cannot tell whether the finance is right. Reading our own code found three things Slither missed, all now fixed:

1. **Funding applied backwards in time** — on a trade left unsettled for 30 days, the owner could have charged 72% of the position instantly. Fixed, with a test (§2).
2. **Nothing tied the discount to the haircut.** The clearinghouse now refuses to deploy unless the weekend haircut is at least the vault's maximum discount.
3. **The calendar disagreed with the analysis** — 48 hours against 65. Both now use 65.

And two limitations we found after the deployment. The contracts are frozen, because the code must match what is on Sepolia, so for each we specify the production fix rather than redeploy:

- **A vault loss is invisible in the event log.** `emit InventoryRedeemed(shares, usdcReceived, usdcReceived > cost ? usdcReceived - cost : 0)` emits zero on a loss, so a depositor reading the log cannot tell "broke even" from "lost $457". Emitting a signed `int256` is a one-line fix.
- **Deposit timing.** Because inventory is held at cost, the gain appears all at once on Monday, so someone could deposit just before redemption and collect a share of a profit they bore no risk for. A real product would add a short lock-up.

The contracts are not audited. We budget $60,000 for one in §6.6, and nothing here should be read as a substitute.

5.3 Gas, and the change we made because of it

Before and after the packing change

Both columns come from the same 25 tests, so they compare like with like. The only difference is the storage layout.

Function	Before	After packing	Saved	%
`acceptOffer` (opens a trade)	244,696	179,359	65,337	**26.7%**
`postOffer`	125,021	103,090	21,931	17.5%
`settle`, paid in tUSDC	71,706	65,977	5,729	8.0%
`settle`, through the vault	168,527	162,798	5,729	3.4%
`closeTrade`	114,845	111,013	3,832	3.3%
`liquidate`	168,231	164,484	3,747	2.2%
Deploying the clearinghouse (once)	2,478,887	2,602,307	−123,420	−5.0%

The first row matches the theory almost exactly: three fewer new slots at 22,100 gas each predicts 66,300, and we measured 65,337. Packing costs a little more to deploy, for the extra masking code, and a position only has to open twice to earn that back.

Then we spent some of it on a correctness fix

The funding fix in §2 made each trade store one more value. Packing kept it inside the same three slots, where a fourth would have added 22,100 gas to every trade ever opened.

Function	After packing	With the funding fix	Added
`acceptOffer`	179,359	185,299	5,940
`settle`, paid in tUSDC	65,977	72,188	6,211
`settle`, through the vault	162,798	171,829	9,031
`setFundingRate`	46,961	54,667	7,706

We accepted that cost: a correct funding charge is worth more than 6,000 gas. Opening a trade is still 24% cheaper than where we started.

What the main functions cost now

Medians from `yarn test`. The ETH column uses an illustrative 10 gwei; our Sepolia transactions ran at 0.05 gwei.

Function	Gas	ETH@10gwei	Function	Gas	ETH@10gwei
`acceptOffer`	185,299	0.00185	`depositSBill`	79,285	0.00079
`settle` (vault)	171,829	0.00172	`settle` (tUSDC)	72,188	0.00072
`liquidate`	170,636	0.00171	`Vault.withdraw`	59,619	0.00060
`Vault.deposit`	108,810	0.00109	`redeemInventory`	57,535	0.00058
`postOffer`	103,061	0.00103	`setFundingRate`	54,667	0.00055
`withdrawUsdc`	95,225	0.00095	`SBill.redeem`	46,034	0.00046
`SBill.subscribe`	90,745	0.00091			
`depositUsdc`	84,143	0.00084			

The same functions on Sepolia, which is a different world

Step	First deployment	Final deployment	Change
`postOffer`	403,079	293,219	**−27.3%**
`acceptOffer`	963,410	639,709	**−33.6%**

Other live costs	Gas
Liquidation, through the vault	546,113
`settle`, through the vault (the vault's first purchase)	406,146
`settle`, paid in tUSDC	105,282 to 203,202
`setFundingRate`	143,875
`redeemInventory`	79,398
Deploying one full set of contracts	42–44 million (about 0.0021 SepoliaETH at 0.05 gwei)

Sepolia charges roughly 3.5× the local figure for `acceptOffer` and about 7× for deploying the clearinghouse. A full run of everything costs about 0.0067 SepoliaETH.

A lesson about gas estimates, learned from a failed transaction. One mock-price update in our live run ran out of gas. The mock stores `block.timestamp`, and this update came straight after another. The estimate ran against the block holding that last update, so writing the same timestamp looked cheap: it returned 42,672 gas when the update needs 52,297. No funds were involved and the price did not change. Both demo scripts now set an explicit limit for updates that follow one another.

5.4 Advanced functionality

The brief lists five features for any topic (a test suite with reverts, a Slither scan, measured gas with a change made because of it, a front end, and an off-chain keeper) and four for hedging (Chainlink staleness and sign checks, on-chain funding settlement, liquidation with a reward plus a keeper, and margin that earns yield). Each feature below has a transaction hash or a file as its evidence, and `submission.json` lists the same set. The brief's last hedging feature is margin that earns yield in Aave V3; ours earns T-bill yield through sBILL instead, which is the last row below.

Feature	Evidence
Chainlink oracle with staleness and sign checks	`Clearinghouse._price()`; 3 tests; rejects any answer over 2 hours old or non-positive
Gas measured and optimised	§5.3: 26.7% saved locally, 33.6% on Sepolia, from a change made *because* of the measurement
Front end	Seven pages, §3.9; 27 mapped errors, 24 guards, 4 confirmations
Test suite with revert tests	`packages/hardhat/test/WeekendMargin.ts`, 37 tests, 25 expecting a revert, 3 randomised invariant runs
Slither scan, every finding fixed or explained	`docs/slither.md`
Off-chain keeper	`packages/hardhat/scripts/keeper.ts`; live settlement `0xab77d5949d13654c01c898635aacaaef394ff454e6cc583a3ffd858b6cf55557`
On-chain funding settlement	`FundingApplied` in `0x6386b7da7d301f822b1ec2765c585bdf6cf096c73d5575d25d15e22d9153d89c`
Liquidation with a reward, plus a keeper	`0x4036f3cc7c2febb3abf3a7e4524d3040effc0cc84fe92f96e1217121b6ee146b`
Weekend vault and calendar-aware margin (our own addition, not on the brief's list)	`SBillPurchased` in `0x6386b7da7d301f822b1ec2765c585bdf6cf096c73d5575d25d15e22d9153d89c`

5.5 The live run

`yarn onchain:all` ran on Sepolia on 1 November 2026, New York time. One command deploys and verifies all three sets, sets up the demo, runs the weekend story, a keeper pass and the liquidation, then writes `submission.json` and `docs/deployments.md`.

What it shows	Result	Proof
The weekend path	Bitcoin moved \$78,025.31 → \$78,462.47, so Fund A owed **\$437.16** while holding only sBILL. The vault paid it for 437.59 sBILL, **the winner was paid at once**, and on reopening the vault redeemed for \$437.59 — a **\$0.44 profit**	settlement, redemption
Funding	Applied inside each settlement at a rate taken from Deribit: about \$0.008 per trade in the weekend settlement	`FundingApplied` in the settlement above
The keeper	One pass posted funding and settled both trades, unattended	keeper settlement
Liquidation (stress set, mock price)	The model predicted \$93,364.46. **The contract refused at 0.1% below and accepted at 0.1% above.** Trader D earned \$467.29, and the vault later made \$10.94	liquidation
The real calendar	During the real weekend, at 02:18 UTC on Monday, the Main set reported *closed*, and a simulated sBILL purchase failed with `MarketClosed`	Read from the contract; shown on the site
Reconciliation	All 28 compared numbers match the chain to the wei	§4.9

Why the vault's profit was \$0.44 and not more, and why that is the right answer. Bitcoin moved 0.56% that weekend, and only 0.9% of the vault's cash was used. That is exactly the idle-cash finding of §4.6, observed live rather than modelled. A demo that happened to catch a 10% weekend would have looked more impressive and taught us less.

What went wrong

- **The liquidation step took three attempts, because of two bugs in our scripts. The contracts behaved correctly every time.** The script first misread the contract's refusal, because it expected the wrong error code. Then a mock price update ran out of gas, for the reason in §5.3. Both are fixed. As a consequence the stress log shows the "just below" price three times, and the mock feed carries one failed transaction. We leave both in the record.
- **Etherscan's rate limit** rejected many verification requests on the first pass. A slower retry verified everything, and `yarn verify` now waits between requests.

The site, used live. On 4 November the whole weekend story was sent from the deployed site through MetaMask on Sepolia, after every flow had been exercised on a local chain with a test wallet. On the demo set the fund's wallet signed every step and the deployer signed only the two weekend switches: trade 2 settled through the vault, which bought 1,686.89 sBILL for $2,122.75 and redeemed it on reopening for a $1.71 profit, and trade 1 settled from cash. On the stress set a trade was opened, settled and then liquidated from the site, for a $499 reward to the liquidator. The reconciliation in §4.9 was read before that run and describes the state at its block.

6 Going to market

This section treats the project as a product: who would use it, why they would trust it, how it would reach them, and whether it pays for itself.

6.1 The market moved toward us while we built

Tokenized U.S. Treasury products held roughly **$14.5–16bn** in October 2026, growing about 125% year over year [5, 6, 7]. Allium counts 91 distinct assets from 36 issuers [5]. Circle's USYC is now reported as the largest single fund at approximately $2.6–3bn, having overtaken BlackRock's BUIDL [8].

Trackers disagree, because on-chain token market capitalisation is not the same thing as fund AUM. We quote a range and cite three sources rather than pick the flattering one.

Derivatives venues then started accepting these instruments as margin: Binance added USYC in July 2025 and BUIDL in November 2025, holding units in off-exchange custody at Ceffu or a triparty bank [2, 4]; Deribit and Crypto.com followed, with Deribit reported to apply a 2% haircut [3, 4].

6.2 What no incumbent does

Every incumbent bridges the gap with an intermediary, and the intermediary re-introduces exactly what tokenization was meant to remove.

	Circle off-ramp	Venue collateral	Weekend Vault (ours)
Liquidity provider	Circle	The venue	**Any depositor**
Permission required	Securitize allowlist	Venue onboarding	**None**
Discretionary	Yes	Yes	**No — contract logic**
Capacity	~$80–100m, one party	Venue balance sheet	**Scales with deposits**
Serves on-chain perps	No	No	**Yes**
Multi-issuer	BUIDL only	Per venue	**Any ERC-20 with a NAV**
Fires automatically at a margin call	No	N/A (ledger entry)	**Yes**
Counterparty risk	Circle	Venue + custodian	Smart contract
Operating history	~2.5 years	1–2 years	**None**

A venue can settle a Saturday loss as an internal ledger entry, because it has a balance sheet to absorb the mismatch. **A bilateral on-chain clearinghouse cannot. The cash has to move.** That constraint is what produces the vault, and it is the position incumbents cannot occupy while remaining intermediaries. Tokenized funds are issued without a clearing layer, and clearing venues operate without owning the collateral. **We build both halves as one system**, which is why the clearinghouse can read its collateral's redemption calendar and route settlement automatically on a Sunday.

6.3 Users

Four segments, ordered by how badly incumbents serve them.

1. **On-chain perpetual traders** (Hyperliquid, dYdX, GMX and similar). No central balance sheet exists to absorb a weekend mismatch, so settlement needs real cash movement. **This is the primary market.**
2. **Bilateral OTC derivatives between funds.** No clearer, same structural problem.
3. **Funds below BUIDL's access threshold.** BUIDL is offered under Section 3(c)(7) to qualified purchasers with a reported $5m minimum [9, 10]. Everyone beneath that line cannot use Circle's off-ramp at all.
4. **Holders of the other ninety issuers.** Ninety-one tokenized treasury products exist [5]; the Circle off-ramp serves one.

What they get that they cannot get today: the ability to meet a variation margin call in cash, at any hour, without pre-funding an idle buffer and without asking anyone's permission. Worth **up to 42bp** against the realistic alternative (§4.7).

6.4 Trust: why a stranger should connect a wallet

Question a risk officer asks	The answer, checkable without talking to us
Can I read the code that is running?	All 16 contracts verified on Etherscan, confirmed through the API; the verified source of the 15 we checked is identical to the repository
Has anyone tested it?	37 tests with one command, 25 expecting reverts, 3 randomised invariant runs; Slither scanned with every finding answered in `docs/slither.md`
Do the numbers add up?	28 values read off the live contracts reconcile to the wei against the model (§4.9)
What can the admin do to me?	Pause *new* deposits and trades, and post a funding rate within a cap fixed at deployment. **Nothing else** — settlement, liquidation, closing and withdrawal all keep working while paused
Who controls the weekend?	`MarketCalendar` has **no owner and no settings**. Nobody, including us, can change when the weekend is
What if the price feed dies?	Any answer older than 2 hours is rejected and the system stops rather than transacting on stale data
What stops me making an expensive mistake?	§2.4: 27 plain-English errors, 24 disabled-with-a-reason guards, two-click confirmation on the four irreversible actions, and the liquidation price shown before you sign

Why the admin-free calendar matters more than it looks. An admin able to repoint the calendar at a contract reporting "always closed" could force every settlement through the vault at a discount, stop fund redemptions, and raise the collateral haircut toward liquidation thresholds — three extraction routes from one key. We removed the key.

And we disclose the exception. The demonstration deployment uses a separately labelled `DemoCalendar` whose weekend is switched by the deployer, so the mechanism can be shown on any day. The production design is the admin-free one.

6.5 Promotion: the first hundred users

Generic community-building is not a plan here, because awareness is not the binding constraint.

- **Issuer integration is step one, and it is not marketing.** BUIDL's token contract blocks transfers to wallets not on a Securitize-administered allowlist [9, 10]. The vault and clearinghouse must be approved holders before a single real user can exist. This gates everything else.
- **Launch where the allowlist is not.** Franklin Templeton's BENJI sets minimum initial investments by chain: $20 on Stellar, $100 on Aptos, $1,000 on Polygon, $20,000 on Avalanche and **$5,000,000 on Ethereum** [11]. Our Ethereum design sits in the most restrictive tier. **A cheaper chain solves the access barrier and the gas constraint at the same time.**
- **Seed the vault ourselves.** Two-sided market, cold start: no vault, no settlement guarantee; no traders, no fee income. The first $1m of vault capital has to come from the operator.
- **Integrate rather than acquire.** The realistic route is as a settlement module inside an existing on-chain perpetuals venue, not as a destination users navigate to.
- **Point the incentives at the scarce side.** Hedging funds arrive on their own, because the alternative costs them up to 42bp. Depositors do not: they are asked to accept T-bills plus about 40bp for contract risk from an operator with no history. So **the incentive budget goes to depositors**: the protocol waives its 25% share of the discount for the first year, lifting the depositor's return from 4.41% to 5.76% and costing us revenue we would not have earned at sub-scale volume anyway.

The token, and why we deliberately did not run a coin campaign

Our minted token is **sBILL**, the ERC-20 tokenized T-bill share. It is the collateral the system exists to clear, not an instrument of promotion: it has a NAV, it is redeemed at that NAV, and nothing about it is speculative by construction.

We considered a governance or reward token and rejected it for a reason specific to this product. **The entire value proposition is that a fund can post collateral and be certain what it will realise.** A token that subsidises deposits makes the vault's advertised return partly a function of that token's price — which re-introduces exactly the volatility the customer came here to remove. A depositor earning "4.41% plus an uncertain amount of a governance token" cannot price the product against T-bills, and pricing against T-bills is the only comparison that matters.

So our promotional asset is the live reconciliation, not an airdrop: 28 numbers read off deployed contracts matching the model to the wei, and a weekend settlement anyone can replay on Etherscan. For risk officers, a verifiable number is more persuasive than a marketing campaign.

6.6 Business model

Where the revenue comes from

The vault buys collateral at NAV minus a discount while the issuer is unreachable and redeems at full NAV when it reopens. It earns the discount *plus* the interest the asset accrues while held — tokenized treasuries accrue continuously, weekends included, even when they cannot be redeemed. Per $1 of vault capital, with the pool sized to cover 99% of weekends (24.6% utilised on average) and a 4.01% yield:

Discount	Fee income	Carry	Total	
10bp (as deployed)	1.28%	0.38%	**1.66%**	loses to T-bills
28bp	3.58%	0.38%	**3.96%**	matches T-bills
42bp (our price)	5.38%	0.38%	**5.76%**	before our share
44bp	5.63%	0.38%	**6.01%**	T-bills + 2%

We price at 42bp, the top of the band, and the protocol takes 25% of it. That leaves depositors 31.5bp, which the model turns into **4.41% a year against 4.01% on T-bills**.

Two consequences, and we state both. First, the fund's 42bp ceiling sits *below* the 44bp the vault would need to pay depositors a conventional 2% risk premium — **at no price does this product clear a conventional hurdle rate.** It clears a T-bill-flat hurdle with about 40bp to spare, and that is the accurate description of the opportunity. Second, pricing at the customer's ceiling leaves no room to absorb a rate move, which is why rate dependence is a first-order risk in §6.8 rather than a footnote.

What it costs to run, and the break-even

Annual cost	Amount	Basis
Infrastructure and keepers	$24,000	Hosting, RPC and monitoring. Keeper *gas* is only about $1,900 a year at 100 open trades on an L2
Security audits	$60,000	Mid-range for a focused DeFi protocol; published 2026 guidance spans roughly $15k–$100k [15]
Legal and compliance	$120,000	Entity, counsel, and the issuer agreements §6.5 shows are mandatory
Team	$300,000	Two engineers
Total	**$504,000**	

Revenue has two legs. The **vault leg** is our 25% share of the discount actually earned, which depends on how much collateral is sold through the vault — on average 2.50% of a hedge's notional per weekend (§4.6). The **clearing leg** is 1bp per side, charged each time a position is opened or rolled, assumed twelve times a year. That sits well under the 4.5–5bp taker fees at Hyperliquid and dYdX [16], which is appropriate: we are a settlement layer beneath a venue, not the venue.

Per $1m of hedged notional, per year	
Vault fees (25% of a 42bp discount)	$1,366
Clearing fees (1bp × 2 sides × 12 turns)	$2,400
Total	**$3,766**

Break-even is $134m of hedged notional, supported by a $26m vault — that vault being about 0.2% of the $15bn tokenized treasury market. In users, that is about 134 funds hedging $1m each, or roughly 1,700 open positions at the demo's size of 1 BTC. At a $200m target the protocol earns **$753,277** against $504,000 of costs, and the vault behind it needs $39.4m of cash, which is 19.7% of notional — the level that covered 99% of historical weekends when longs and shorts share one pool.

Note which leg actually carries the business: **clearing fees are 64% of revenue.** The vault is what makes the product possible, but a flat per-trade fee is what pays for it. A reader who disbelieves our discount analysis entirely still finds a business at $210m of notional on clearing fees alone.

6.7 The constraint that decides where this can ship

Our keeper settles each open trade hourly. This cost is absent from the financial analysis and it is decisive. Using the measured 72,188 gas for a settlement paid in tUSDC, at 10 gwei and $3,000 ETH:

Open trades	Ethereum mainnet	L2 (∼1000× cheaper)
2	$37,942	$38
100	**$1,897,101**	$1,897
1,000	$18,971,006	$18,971

At 100 open trades, mainnet gas alone costs $1.90m a year. Those trades are perhaps $8m of notional at the demo's size, which earns about $30,000. **The gas is sixty times the income. The product cannot exist on Ethereum mainnet.**

The same arithmetic decides whether liquidation even works. The reward is 50bp of notional and `liquidate` costs 170,636 gas, so on mainnet a liquidator breaks even at about **$1,024 of notional** and below that no rational keeper acts. On an L2 the threshold is about **$1**, so the incentive holds at any size a user would trade.

This is the most consequential finding in the go-to-market work, and it came from the gas table. It changes no contract. It determines where the contracts can be deployed. And it compounds with the BENJI access tiers: the cheaper chain is simultaneously the regulatory entry point and the only viable gas regime.

6.8 Risks

1. **Incumbents extend downward.** If Circle widens its off-ramp beyond BUIDL, or on-chain venues negotiate their own issuer arrangements, the gap we occupy closes. **We consider this the most likely adverse outcome.**
2. **Holder restrictions — the risk the professor asked us to address.** Tokenized funds restrict who may hold them. BUIDL enforces a Securitize allowlist *at the token contract* [9, 10]; BENJI shares are held in KYC'd registered accounts with chain-dependent minimums [11]. Our vault and clearinghouse would both need approved-holder status, vault depositors might need KYC, and Monday redemption depends on a partnership with the issuer. **Our design limits the damage by construction: sBILL moves only to the vault or back to the fund, never to a liquidator**, so no unapproved transfer path exists. We decided as a team not to write allowlist code — it would have been untested scaffolding against a mock — and to state the requirement instead.
3. **A downturn exhausts the vault before it threatens the fee.** Four of the seven historical crises in §4.8 exceed a 95th-percentile vault. **This is the binding constraint, and it is a capital question rather than a pricing one.**
4. **Thin economics.** The viable band is 28–42bp and disappears entirely against a fund that sells T-bills every Friday.
5. **Interest-rate dependence.** At 2021 rates of 0.05%, a user of this product would have *lost* about $2,222 a year on a $1m hedge. The product requires meaningful short-term rates.
6. **Gas regime.** Mainnet is not viable, so the business inherits the security and liquidity assumptions of whichever L2 it ships on.
7. **Regulatory ambiguity.** Reported September 2026 CFTC staff guidance legitimises tokenized money market fund collateral for *swap dealers* — that is, for the intermediated model we are

positioned against [4]. We could not confirm this item against a primary CFTC document; see Appendix D.

8. **Exploit.** The contracts are unaudited. Slither's 26 findings are answered in §5.2, and our own review found three finance bugs a scanner cannot see. An external audit is budgeted at $60,000 and has not been performed.
9. **No operating history.** Every competitor named here has one to two years in production. Our evidence is a single live run: one weekend settlement through the vault, one liquidation against a mock price, and 28 reconciled values.

7 Summary and what we learned

7.1 The steps we took, in order

1. **Framed the problem as a number.** Not "perps are interesting" but "a hedger holds idle cash because T-bills cannot settle at a weekend — what is that worth?"
2. **Built the end-to-end path first**, as the professor's feedback asked. Six contracts on a local chain: token, dollars, calendar, vault, clearinghouse, and a demo calendar.
3. **Wrote the tests alongside**, including the reverts. 37 tests, one command.
4. **Measured gas, and changed the code because of it.** Packed the trade struct from six storage slots into three. 26.7% off opening a trade locally, 33.6% on Sepolia.
5. **Read our own code looking for the worst thing an owner could do**, and found the funding bug. Replaced the calculation with a running total and accepted 6,000 gas to fix it.
6. **Ran Slither**, fixed four findings and wrote down why the other twenty-two are acceptable, one at a time.
7. **Deployed three labelled sets to Sepolia** with one command, and verified all sixteen contracts on Etherscan.
8. **Ran the story live**: funds posted sBILL, trades opened at the Chainlink price, funding was posted, the market closed, settlement routed through the vault, the winner was paid, and the vault redeemed on reopening.
9. **Ran a keeper pass** unattended, and **a real liquidation** on the stress set, with the contract refusing 0.1% below our predicted price and accepting 0.1% above it.
10. **Built the financial analysis** on six years of hourly Bitcoin data, six years of funding, and eleven years of T-bill yields, with every judgement call in one config file.
11. **Reconciled the model against the chain** — 28 numbers, to the wei.
12. **Built the front end**, including the parts that exist only to stop a user losing money: 27 plain-English errors, 24 guards, two-click confirmations, and the liquidation price shown before you sign.
13. **Priced the business**, found that our own deployed fee does not work, and reported that rather than redeploying.
14. **Wrote this report, and two companion documents** — `docs/pricing-and-risk.pdf` and `docs/going-to-market.pdf` — for readers who want every derivation.

7.2 The unrealized P&L strategy, under stated assumptions

The strategy in one sentence. Hold Bitcoin, short an equal notional of perpetual swap at **2–2.6× leverage**, post the margin entirely in tokenized T-bills rather than cash, and route weekend variation margin through the vault — converting an unhedged 16.9% standard deviation into a flat carry of roughly **$343 a month per BTC**, at a cost of about **$3 a month** in vault discounts.

Pre-defined assumptions. Entry $77,853.66; 1 BTC of spot and 1 BTC of short perp; $30,000 of margin posted as sBILL (2.60×); counterparty long with $30,000 of tUSDC; 30-day hold; funding at the median month's rate, 0.32% of notional a month (about 3.8% a year), paid to shorts; sBILL accruing 4.00%; vault discount 10bp applied to 65/168 of each loss; initial margin 20%, maintenance 10%, weekday and weekend haircuts 1% and 3%.

Component, 30 days, 1 BTC	P&L	Where it comes from
Spot Bitcoin (at a +10% move)	+$7,785.37	Mark-to-market on the holding
Short perpetual	−$7,785.37	**Unrealized P&L on the open trade**, read on-chain as `unsettledPnl`
Funding received	+$260.93	Median month's rate on the average notional; longs pay shorts, 20% of months reverse
sBILL interest	+$85.83	4.00% for 30 days on the margin net of half the loss, which is paid in sBILL
Vault discount paid	−$3.01	10bp on the loss, for the 65/168 of the week the market is shut
Hedged total	+**$343.75**	Flat for any move between −31.7% and +25.8%
Unhedged comparison	+$7,785.37	**and** −$7,785 on a −10% move; sd 16.9%, worst case −43.1%

The boundaries of the strategy, which matter more than the centre. Above $97,959 or below $53,171 the trade is liquidated and the hedge is gone. Over 2,099 rolling 30-day windows that happens in **14%** of them with no top-ups at 2.6×, and about half at 4.9×. The strategy is therefore not "short a perp" but **"short a perp and maintain it"**: hedge effectiveness is 97% at 2×, 92% at 2.6×, and collapses to 34% at 4.9×. **Leverage discipline, not the hedge itself, is what makes this work.**

And the vault's side of the same trade. It earns 10bp plus 65 hours of carry on every dollar it deploys, which covers the 6.6bp of measured risk comfortably — but it earns nothing on the three quarters of its capital that waits. At **1.2–1.7% a year against 4.01% on T-bills, the deployed vault is not yet a business**, and §4.6 gives the three fixes.

7.3 What we learned

1. **The most valuable result was the one that contradicted us.** We deployed a 10bp discount, then proved it insufficient for the vault as a business. Reporting that was more useful than any confirmation would have been, and it changed the design roadmap: the open question is no longer "is the fee right?" but "how much capital stands behind it?"
2. **A security scanner cannot read finance.** Slither's one High-severity finding was a false positive about a modulo. The genuinely dangerous bug — an owner able to charge 72% of a position in one transaction — was invisible to it and obvious the moment we asked "what is the worst thing the owner can do?" We would ask that question first, next time.

3. **Gas is a product decision, not an engineering detail.** A table of gas measurements told us the product cannot exist on Ethereum mainnet. No amount of financial modelling would have surfaced that, and it is the most consequential thing we found.
4. **Making the model match the chain to the wei was harder and more valuable than expected.** It forced us to replicate the contract's rounding exactly, and the same discipline — putting the contract's constants beside the model's — is what surfaced the 48-hour against 65-hour calendar mismatch. **Reconciliation is a test, not a formality.**
5. **Constraints produce designs.** The course's requirement to mint a token is what pushed us from "a perp" to "a perp margined with a tokenized bill" — and the weekend problem, the vault, and the whole interesting half of this project followed from it.
6. **Measure before you optimise, and measure again afterwards.** Our instinct about where the gas went was right; our instinct about the discount was wrong. Only one of those was knowable without data.
7. **State the limits.** The mock token, the deployer's demo switch, the mock stress price, the missing insurance fund, the three liquidation attempts. Every one is in this report, because a system that cannot be criticised is a system nobody can trust.

7.4 Acknowledgements

The weekly assignments built up the pieces one at a time: hashing, mining, signing and deploying one contract a week. This project is the first time all of them had to work together, against real market data, with real consequences for getting a formula wrong. The brief's instruction to think like a founder changed what we built: it is the reason we costed the business, found the gas constraint, and discovered that our own fee was wrong.

We thank Professor Radnay, whose feedback on our proposal shaped four parts of the finished project: the two calendars, the two-hour staleness limit, the vault economics section, and the going-to-market plan. We also thank TA Hina Tomar for support throughout the course. We finished more convinced than when we started that there is a real product here, and better informed about how narrow the path to it is.

8 AI Use

Course policy is "Welcome with Attribution," and the brief notes that because AI makes code cheaper to write, the bar for design, testing and analysis is higher. We agree, and this section gives the full account.

Tool used: Claude Code (Anthropic), run from the terminal with access to this repository.

What	What the AI did	How we checked it
Contracts	Drafted all six, and the deployment script	37 tests we specified; Slither; a line-by-line read that found the funding bug the AI had written and the tool had missed
Tests	Drafted the suite from behaviours we named	We required reverts and invariants explicitly; the randomised seeds are run and reproducible
Scripts	Keeper, demo, liquidation, evidence, verification	Every one was run live on Sepolia with Sai approving each command; two script bugs surfaced *in* the live run and were diagnosed and fixed
Front end	All seven pages, the error map, the guards	Every flow exercised on a local chain with a test wallet, **then the whole weekend story and a liquidation were sent from the deployed site through MetaMask on Sepolia on 4 November**
Notebook	Drafted the analysis from a plan we wrote (`docs/ANALYSIS_GUIDE.md`)	**The reconciliation is the check**: 28 values matched to the wei against the deployed contracts, and the cell errors rather than reporting a near miss. Every assumption was reviewed and several were changed
Documents	Drafted this report and the two companions from our material	Every number traced to the notebook, the gas log, the test output or the chain. Figures recomputed independently of the notebook as a cross-check, which surfaced two definitional discrepancies that we resolved in favour of the stricter definition

Where the AI was wrong, and how we caught it.

- It wrote the original funding calculation, which applied a new rate backwards in time. We found it by reading, not by testing. The running-total design in §2 replaced it.
- It wrote a 48-hour calendar against a 65-hour analysis. We caught it by putting the contract's own constants beside the analysis, which is also what the reconciliation now enforces automatically.
- The script it wrote relied on the node's gas estimate, which was too low for a repeated mock-price update, and the transaction failed on Sepolia. We diagnosed the cause (the estimate ran against a block that made the storage write look free) and set an explicit limit.

What stayed human. The problem choice and the framing. The decision to build the end-to-end path first. Every on-chain command on Sepolia, approved and password-typed by Sai — **the agent never saw a private key or the password**. The judgement calls in the analysis, and the decision to publish the result that contradicted our own deployed parameter. The choice not to issue a reward token. And the decision to state every limit rather than round the edges off.

Division of work. Sai Kishore owned the contracts, tests, scripts, deployment, verification and front end. Swastik Mishra owned the financial analysis, the pricing and risk work, the going-to-market plan and this report. Both of us reviewed the other's work, and the tests and the reconciliation check both.

A Key transactions on Sepolia

Contract addresses are in §3.5. These eight transactions are the ones listed in `submission.json`; the complete step-by-step logs are in `packages/hardhat/demo-log.sepolia-demo.json` and `demo-log.sepolia-stress.json`.

What it shows	Transaction
A fund posts sBILL as margin	0x5132c08f97abdb8c6e0a5a0e506ffb6f2e6de2d7db16810c276b1e0cca3bd81f
A trade opens at the Chainlink price	0x5e5802a28e5fe9b9dd1d6d5adbe02a9f46741e2c6cf655c931930909173ba7a9

C Metadata and JSON artefacts

C.1 `submission.json` — structure

The full file is in the repository root. It follows the template at the end of the brief and carries:

Key	Contents
`team`	`"Team 9"`
`members`	Sai Kishore (`sp8744`), Swastik Mishra (`sgm9198`)
`topic`	`"Hedging with perpetual swaps"`
`repository`	https://github.com/Psaikishore/WeekendMarginDemo
`tag`	`"final"`
`network`	`"sepolia"`
`token`	ERC-20, `"Tokenized T-Bill Share (sBILL)"`, `0x2aff...6720`
`contracts`	All **16**, each with its address and a one-line role
`transactions`	The **8** key transactions in Appendix A
`features`	The **9** advanced features of §5.4, each with a transaction hash or a file path
`video`	The narrated walkthrough

C.2 Per-contract metadata

Each of the sixteen files in `packages/hardhat/deployments/sepolia/` contains the full Solidity metadata object: compiler version and settings, the ABI, creation and deployed bytecode, immutable references, the storage layout, `devdoc` and `userdoc`, the constructor arguments, and the complete deployment receipt. The front end's typed ABIs are generated from these into `packages/nextjs/contracts/deployedContracts.ts`, so the application cannot drift from what is deployed.

C.3 Configuration

File	What changing it does
`config/protocol.json`	The eight contract settings. **Changing one means redeploying**, because the code must match the chain
`config/assumptions.json`	Every judgement call in the analysis. Change and rerun the notebook; nothing is typed into a cell
`config/analysis_results.json`	Written *by* the notebook, read by the app's Economics page

D Source confidence for the market claims

Much of the competitive information in §6 is secondary reporting, and sources conflict. We record confidence rather than present every claim as equally established.

Claim	Confidence	Basis
Circle BUIDL→USDC contract exists, April 2024	High	Primary press release [1]
BUIDL restricted to qualified purchasers, allowlisted	High	Multiple sources agree
BENJI chain-tiered minimums	High	SEC filing [11]
Tokenized treasuries $14.5–16bn	Medium	Trackers disagree; we quote a range
Binance USYC July 2025, BUIDL Nov 2025	Medium	One source dates USYC to 2024
Deribit 2% haircut on BUIDL	Medium	Single secondary source
Deribit / Crypto.com integration date	**Low**	Sources give Q1 2026 and July
Circle reserve ˜$80–100m	**Low**	2024 figures, possibly stale
CFTC guidance, 24 September 2026	**Low**	**Not confirmed against a primary source**

E Reproducing everything in this report

Command	What it produces
`yarn install && yarn test`	The 37 tests of §5 and every gas figure in §5.3
`yarn start`	The front end of §3.9, reading live Sepolia. No wallet needed to browse
`yarn chain` then `yarn onchain:all --network default`	The whole system on a local chain, with no keys. The mock price moves by itself
`jupyter lab docs/analysis.ipynb`	Every figure and table in §4. Only Section F needs the network
`python3 docs/stress_weekends.py`	The stress-weekend table of §4.8, from the cached data, written to `docs/report_stress.tex`
`python3 recon_table.py` (from `docs/`)	Appendix B and the live-state numbers of §4, from the notebook's reconciliation output
`yarn onchain:all`	The full Sepolia run of §5.5. **Needs the deployer key; already done**
`yarn evidence`	Regenerates `submission.json` and `docs/deployments.md` from the on-chain logs
`slither contracts/...`	The scan of §5.2; exact invocation in `docs/slither.md`

The "before" column of the gas table is commit `4ad4251`: check it out in a separate copy and run `yarn test`. All four data series are cached in `docs/data/`, so the analysis reproduces with no network access at all.

Companion documents

Document	What it adds
`docs/pricing-and-risk.pdf`	Every derivation behind §4.6 and §4.10: the decomposition term by term, a line-by-line provenance table for every figure quoted anywhere, the June 2022 case study, and the regime stress in full
`docs/going-to-market.pdf`	The long version of §6: competitive landscape, the costed P&L, the gas constraint, and the risk register
`docs/analysis.ipynb`	The financial analysis itself, runnable
`HOW_IT_WORKS.md`	Every contract, formula and failure case in plain English
`docs/slither.md`, `docs/gas.md`	The scan and the gas measurements, finding by finding
